It is quite unnecessary for us to follow the narrative of this case in all its details. The patient, between the period of the operation and that of his cure, suffered a most kind of convalescence, which at first slowly consisted of difficult deglutition, severe pain all over the right side of the head, together with of the arm, frequent rigors, and fevers. In the afternoon blood began to flow through the ligature, and, as the bleeding had not ceased when an hour's pressure with the hand the dressings were removed, and the blood found to proceed not from any particular artery, but from all the wounded surface. The wound was again sprinkled with pine resin, which was covered with stapes, and a bandage; two sanguine scars also directed to keep up pressure with moderate. The day after the operation the febrile symptoms rose high, but in two days subsided again. On the eighth day all the ligatures came away, even that which had secured the tumor, and a large quantity of fresh matter was discharged. Soon afterward a considerable fetid matter, which however was mixed with grunge and some powder. On the 16th day another serious hemorrhage was occasioned by a catarrhal touch, and life was endangered by the loss of not less than two pounds of blood. The bleeding which came from the upper angle of the wound was stopped by means of a piece of sponge dipped in rectified spirit, and covering the wound and dressed the whole neck with compresses wet with vinegar, pressure being also kept up on the sponge with the hand. The dangerous state of the patient may be conceived when it is known, that there was now a deadly paleness of his whole body, languid eyes, dimness of vision, loss of hearing and speech, and extreme prostration of the vital powers. With the aid of judicious treatment, however, he rallied, and in the end left the hospital quite cured.

In another case reported upon by M. Moreau, the dissection was even easier, owing to the extensibility of a portion of the distal lobe of the thyroid gland. It fell back in the transverse processes of the cervical spine; but, after the third day from the operation, the progress to recovery was not interrupted by any bleeding. (See *Graville's Journ.* t. 2, p. 227, &c. or the *Quarterly Journ. of French Med.* N. 19.)

There can be no doubt, that the method adopted by M. Moreau was well calculated to obviate the great source of hemorrhagic danger, viz. the *Arteria*. As long as it was possible he took up every vessel which he exposed or divided; and when this plan could not be continued, he tied the base of the tumor or he detached the enlarged gland from the larynx. This tying of the base of the swelling, though sometimes practised on other occasions, as in the removal of diseased uterine glands, constitutes the chief peculiarity of M. Moreau's method.

A case has been published in which Kluge removed a very large thyroid gland. The patient, a boy, eleven years of age, died on the operating table. (See *Journ. des Chir. & P.* p. 120, *Ann. Berlin*, 1829; or the *Quarterly Journ. of Foreign Medicine*, vol. 5, p. 391.) On the whole, I consider the practice of tying the thyroid arteries is generally a valuable measure, than the removal of the enlarged gland with a knife. (See *Moniteur*, 26.4, Jan. 44, p. 383.) But now that the efficacy of the preparation of iodine, in such cases of

hemorrhoids has been fully proved, it is to be hoped that few cases will present themselves in which either hemorrhoid will be absolutely necessary.

TIC DOULOUREUX. This term is used to signify a disorder, the most prominent character of which consists in severe attacks of pain, affecting the nerves of the face; most frequently the filaments of that branch of the fifth pair which comes out of the lateral oblique foramen; but sometimes the other branches of the fifth pair, and occasionally the opposite filaments of the opposite side of the sensory nerve, which are distributed upon the face. The complaint is not constant, but occurs by violent paroxysms, which away is denominated in different instances. It is the *neuritis dolorifica* of Sauvages; the *facies nervosa nervosa* of Dr. S. Forster; and of that order of diseases which Professor Cuvier has to apply denominated *neuritis* (from *neur*, a nerve, and *itis*, pain); for it should be known that many other parts of the body are subject to a similar affection.

The first accurate description of the disorder was published in the year 1774, by the late Dr. Ponsingh. (See *Med. Opin. and Essay*, vol. 3.) It is not now, however, as is generally stated, that he was the first author who noticed the complaint. This, indeed, is an error being correct, that he even had an account of an epidemic disease long ago by Lentin, for the relief of the disease (see *Ann. 26 de la Faculté de Médecine*, 1706); and this identical case actually became a subject of hot dispute between the physicians and surgeons of the English metropolis. (See a *Thesis*, entitled "De *affectione paresthetica capitis faciei dolorifica attingente partem oculi maxillarem nervi quinti parvi*," &c. by Professor Follard, 1766, *medicæ jurisprudentiæ*.)

The disorder is occasionally a kind of being divided into four species, called by the French *facies nervosa*, *sub-oculorum*, and *neuritis*, and *neuritis*, and the *neuritis* of the *facies nervosa*.

In the *facies nervosa* the pain usually begins in the distance of the supra-orbital foramen, extending at first along the branches and ramifications of the frontal nerve, distributed in the soft parts upon the forehead, and afterwards descends in the direction of the trunk of the nerve towards the bottom of the orbit. In a more advanced stage, the conjunctiva, and all the surface of the eye participate in the effects of the disorder, and become affected with chronic inflammation, which is denominated as a particular species of ophthalmia. At length the pain passes beyond the distribution of the branches of the frontal nerve, and affects all the corresponding side of the face and head. It becomes if it extended itself to the facial, sub-oculorum, maxillary, and even to the temporal and occipital nerves, through the communications, naturally existing between the branches of all those portions of sensation. Each year pain produces a spasmodic contraction of the eyelids, and a copious effusion of tears.

The sub-oculorum neuritis is first felt about the sub-oculorum foramen. The seat is probably in the nerve of this name, and the pain extends to the lower eyelid, the inner canthus of the eye, the space about the eyebrow, the brow-ridge, cheek in general, ala of the nose, and the upper lip. At a later period, the pain appears to extend backwards to the trunk of the nerve, and those branches which give off it in its passage through the sub-oculorum canal. Hence, pains are then experienced in the upper teeth, the zygomatic fossa, the palate, tongue, and within the cavity of the nose. As the disorder advances, it may extend, like other neuritis of the face, to all the branches of the head. Distant paroxysms, when the disease is fully formed, are abundant, and usually takes place. In general, the strongest toothache denotes the proclivity, when, in the head, the pain arises from another cause, namely extracts several of the teeth.

The distribution of the lower jaw or maxillary neuritis, is usually first felt about the separation of the anterior surface of the maxilla superior, and it extends to the lower lip, chin, neck, teeth, and temple. This form of the complaint is more common than the preceding; but when it has prevailed some time, it is equally formidable for its intensity.

With respect to the neuritis of the facial nerve or points due to the sensory nerve, it is a case which very soon gives rise to the disorder called from the other species of the disorder. The pain is in an early period are no longer confined to the passage of the principal

branching of this nerve between the parotid gland and taste of the jaw. The tuberosity communicates with the pith of the tooth with the rest of the nerves of the face seem to lackling the extremities of the dentate, so that the ligum is soon felt over the whole side of the head. The original source of the dentals can only be detected by carefully considering the progress of the compound in all its stages.—*See* *Dental, Treatise des Maladies Vegetatives Chirurgicales*, t. 3, sect. 7, p. 224, &c.

The disorders may be known from their origin by the personality being attacked by the slightest touch, by the excitement of the circulations, and the extreme violence of the pain. In acute rheumatism, also, there is fever, with redness, heat, and generally some degree of swelling; and in chronic rheumatism the pain is tedious, long continued, and often increased at night; some of which symptoms characterize the disorders.

It may easily be distinguished from leucostoma by the pink color of the margins of the branches of the affected nerve.

It is known from the experience by the comparative diagnosis of the pneumonias, the quickness of their appearance, the intervals of entire ease, the starting of the pain in the breast of the pleural nerve affected (the nervous period) and the exciting kind of pain, and the control of everything which was taken accordingly the course.

3 The causes of the discharges may be said to be in general unknown; but at least a few instances are recorded, which appear to be the consequence of external violence, wounds, contusions, &c. It is supposed in case of the breasts, that distant irritations, especially of the spermathecae, either produce this disease, and that Sir M. Baillou has met with instances where the discharge of portions of disorganized bone, even from a distant part, has cured the complaint.—*Med. Chirurgica*, Vol. 3, cas. 25. The difficulty of placing implicit reliance on such observations depends on the fact, that disorders frequently exist together in different parts, without having any kind of connection with each other, and becoming curable in isolation.

A modern writer has related a very curious instance of a contagious disease in thrush, where the infection proceeded from the judicious use of a small bit of sugar in the usual way. (*Denmark*, in *Med. Cur. Trans.*, vol. 4, p. 85.) Dr. Perry announced the case in increased virulence, or the transmission of blood (perhaps accounting for its malignancy) in the insertion of various speciousnesses, etymology of the native affluents, (*Annals of Philadelphia and Tennessee*).

Mr. A. Cooper states, however, in his lectures, that the worms in this disease are certainly not in an advanced state; they are larvæ of their natural colour, and seldom encased than encysted. The latter fact was contradicted in a dissection made by Mr. Thomas. An occasional dissection of the worm is composed of larvae, Dupont, &c., but whether from dissection or actual observation I am uncertain.

Stimulating, invigorating, Diuretic, cardiac tonic, respiration, healthy, friction with essential oil of spruce (Edinb. Med. and Surg. Journ. and N. J. electricity, opium in large dose, the anæsthetic solution, and a variety of antispasmodic medicines, are the principal means which have been tried; but for the most part, they only afford partial and temporary relief. Lascaris has reported two cases which were cured by bath joined with opium and sulphate of ether, and two other examples which yielded to pain composed of the extract of hyoscyamus, valerian, and peroxide of zinc.—*Lancet* (Lond. Gaz. Medica 1842, 20, 64, 164, 171). The Indians, too, often have tried and often failed. Two cases, in which it answered in doses of two grains at a time, three and a half, were lately published by Mr. Thompson of Winchester.—*Brit. Land. Med. Repository* for July, 1822. M. Paraguet cured a prostration of the lower extremities, with the sulphate of quinine, in graduated doses, were directed with occasional doses of orange-flower water and spirits, and when in due doses, the medicine being continued after dinner or evening doses for a short time. M. Dupré has also published various observations respecting the use of plants of yarrow as a very powerful remedy for rheumatism in the viscera: *Lancet*. The goodness of Dr. Raley is also in favour of magnesia, and his opinion is backed by two cases in which he tried the medicine with success.—*See Thompson's Journ. of Physic*.

[illegible]

In 1901 Mr. R. Hutchinson published some essays tending to prove that the schoolmaster in his life is done of 1/10, or 1/1, two or three times a day, it being as harden remedy for his discomfort. In fact, the estimate of opinion be accepted, the teacher is a person whose more repugnance than any kind he is comes to this complaint. It is highly endorsed by Sir A. Cooper in his lectures. Yet, as we saw, in some, a shared critic noted all the pains with distinct; in all the cases, he says, the first year that in 1/10, or 1/1, three times a day, he comes. The teacher, indeed, when exposed to the pains, he was more than slightly relieved. This, as he notes, is in itself almost a proof of the condition being very hard, but when we find that Mr. Hutchinson's remedy (which he says is to be taken off immediately when the attacks to the schoolmaster is commenced in the day, and outside the school, purgatives and of course likely to debilitate the nervous system, we may somewhat doubt the role efficacy of this in a more serious case. But we see, that the nature of these would yield in less time to the plain common sense of Mr. Alverth's by sending the teacher, paid without treatment, calculated to relieve the inflammation which in most cases, he says, usually affects the nerves themselves. (See *Ed. Intelligencer* for 1881, p. 472). The latter suggestion, however, is rather unusual to what is now commonly known.

The strongest fact in favor of the real efficacy of an ablation of nerves, is evidenced by the fact, that a severe case was benefited soon after the operation, but by accident, the subcutaneous plexus was thus gone. Six days, during which the spasms occurred with their usual violence and frequency, had when the tract was given again, the good effect rapidly reappeared from it obtained.—*See Med. and Surg. Journ. for Feb. 1823.*

The operation of dividing the trunk of the uterine artery, and even of disconnecting a portion of it, so as to prevent subsistence of a longer source of vessels at the ends of the artery, is a plan which has sometimes been combined with permanent bleeds. Thus, one case of the three instances of the EVA part of uterine artery, divided at the point where it joined the trunk of the face. But before having recourse to this means, the Surgeon should be sure that the previous means which he is about to employ and divide is really the principal part of the disease; for when of an extensive of the face generally are affected, or when the branches of the plexus differ, the operation is unavailing. In a few cases, however, it has been successful. In fact, it must be observed, that the operation has had many failures and triumphs; either from the cases not having been truly considered, or from the surgeon not having a perfect idea of an exposed vessel. Richerand, Delpech, and even of an leading surgeons in France, express their preference to the application of the mode in passing, which, they say, gives more frequently successful results than the EVA. This should be done directly over the uterine artery, which the artery crosses in the substance of the clitoris, and Richerand asserts, that he has a bleeding the pulse may always be found, or at all events rendered supportable.—*Narrative, Chap. I. §. 4. p. 106, 107.*

Delpech also affirms that the method of the artery very often fails, and that hence and the symptoms of the catarrh have been attended with the most serious.—*See French Med. Jour., 2, p. 215.*

The displacement of the os uterine by burning, and thus being, however, by very objectionable. And yet, still there is no positive evidence of the efficacy of this method over the use of the knife. I consider, still, Colver and Delpech have acted only in great ignorance of the extreme partiality of the French surgeons to the probe, and cauterization. Delpech did, however, observe, that when the probe went into the consequence of a disease or inflammation, it was

Bichat describes the following as being the common plan: the tongue is vigorously moved very widely and depressed the tongue with any flat instrument, which is to be held by its anterior end. The operation is then to take hold of the diseased tonsil with a forceps, and with a narrow scalpel, having the blade full on the whole covered with rap, he now seizes it as a point of the tonsil is caught to be taken away. In removing it, it is depressed sufficient to cut as a line without injury of the tonsil (prolongation paid). Any other motion, tearing instead, should not be taken away. The operation being finished, the patient is frequently to wash his mouth with proper gargles.

The preceding method has been adopted by Broust. However, one objection is urged against it, viz. that when the end of the knife is conveyed far into the mouth it may be mistaken, not (as has been alleged) for the internal maxillary artery, the backward situation of which completely keeps it out of all danger of being wounded, but to the membraneous covering of the palate is a pitfall not corresponding to the knife. Dever thought this objection was the more feasible, as when the knife is introduced into the mouth, the danger of the above mistake is considerably increased for a general reason, which seems to affect every part of the mouth. Hence, that eminent surgeon used to employ, for the removal of diseased tonsils, an instrument which was first invented for dividing cysts of the bladder. It consisted of a sweeping blade, which was included in a silver sheath. The latter had at its extremity a kind of notch, in which the point about to be withdrawn was secured. The rest of the instruments were similar to those previously used. Dever's procedure is as follows:

1. The patient being seated on a high chair, with his head supported on an assistant's breast, he is to open his mouth very wide, and the lower jaw also be kept thus depressed by some solid body placed between the teeth, and held there by an assistant.

2. The tongue is to be kept down with a broad spatula.

3. The surgeon is next to take hold of the tonsil with a double hook, with which he is to raise and draw it a little towards him. He is then to take the above cysticoid and put the notch in the point as a level with the parts where the incision is intended to be made.

4. When the portion which is to be cut off is engaged in the notch, the operator is to draw the point towards him as far as it can go, and press the double hook against the tonsil below it. The knife being next pushed against the tonsil, the necessary section is accomplished. When the division is accomplished, which is painful, but liable to happen when the diseased gland is of considerable magnitude, the blade is to be drawn back, and the wound is completed by applying the instrument to the second which it has already made. Substituting even a good operation may possibly become requisite.

5. The patient is to be directed to wash his mouth. Bichat states, that this plan of operating, adopted by Dever, is as simple and easy as the method above related, with the advantage of being safe. Such is the construction of the blade of the instrument, that when it enters into the mouth it presses against, and steadily holds, the parts which are to be divided, an advantage which enables the knife to remove safely, under the action of which the parts are quite safe. Hence, there is difficulty in carrying them. When the introduction of the instrument from above downwards is difficult, it is better to withdraw it, and when turning the point in the requisite direction, pass it from below upwards. In general, however, the first of these methods is preferable, because the gland, when half cut through, cannot now get back and obstruct the view, thus, as to being on danger of a sudden suffocation; a circumstance which Whiston and Mercat saw happen. With the view of preventing this occurrence, Lewis recommended the common scalpel to be used, with its edge directed upwards, as has been advised for the above instrument; which little contrivance, however, being according to his own account, next easy and safe, meets the purpose. Besides the advantage of being cut with parts which are to be cut, it has that of not confining them, like moderate instruments of this nature, as, for instance, Wilson's; and the oblique disposition of its blade enables it to divide even in the manner of a saw.

This instrument, as Bichat shows, is certainly improving the number of surgical instruments, a thing which all the best modern surgeons endeavor to avoid. But it is to be recollected, that this instrument is not exclusively applicable to any particular operation. It may be employed for cutting away the tonsils and the tongue during operations done in the pharynx, larynx, and trachea; and, in various other circumstances, parts of the case of this mode of introducing some other instrument, and various methods in which it is used are deeply influenced in different cases, as the body, unless instruments introduced separately might injure parts which should be avoided, or where the bone of the base of the skull is to be removed, or where it is to be accomplished. The latter object cannot easily be effected by means. When the bone of the base of the skull is to be removed in the neck, one part is due to be divided, and then another, all as which is done in the neck.

In England, when a diseased tonsil is to be cut away, surgeons generally prefer a common scalpel.

As a general practice, I consider that the removal of an enlarged tonsil is a better practice than the extirpation of it with a ligature, which also sometimes happens very well, and, perhaps, in children, and small patients, may merit the preference. The chief reasons for the ligature are, that in operation is rather tedious, sometimes productive of a great deal of hemorrhage, and on the whole as painful as the knife.

Moreau having once adopted this plan, very severe pain and inflammation ensued; the difficulty of swallowing and breathing compelled him to suspend the operation at the place where the ligature was applied, and all the bad symptoms immediately ceased. Besides, when the ligature is used, there is no cutting of blood from the vessels, a circumstance which tends so much to diminish the inflammation. The loss of the swelling is also sometimes greater than its upper part, and does not admit of being properly surrounded with a ligature. And when it has a narrow base, it can then be so easily removed with a scalpel, or with Dever's instrument, and with so little pain, that one of the last modes is generally preferred.

The ligature, however, has had its advocates. Hunter considered it inevitable cause. Sharp praised it, and others approve of it; and the plan of employing it has been various in the inventive genius of the different practitioners of the practice. Some resemble of Lenoir's double cascade, which is furnished with a silver wire, in which the tonsil is to be engaged. By twisting the instrument, the diseased part becomes constricted. Some, after passing the wire of a ligature over a kind of instrument, take hold of the lower part, push the ligature over the enlarged part, which they fix, without having any means of increasing the constriction afterward. Others employ Dever's instrument for getting the ligature over the tonsil. Still, Cooper, who prefers the pedicle, carry, and then passes the ligature with it behind the enlarged tonsil. The pedicle being then removed, the knot is made with care, so that the ligature is not long enough for the purpose.

Moreau employed an instrument which the French call an *entrouvert*, which is in fact nothing more than a long, narrow, round piece of silver, terminating at one end in a little ring or hole, and at the other in a kind of grooved mouth.

1. The patient was seated on a high chair as in the first method, with his head supported on an assistant's breast; his mouth was opened very wide, the tongue depressed, and the diseased tonsil taken hold of with a double hook.

2. The surgeon took the *entrouvert*, in which the ligature had been passed, so as to form a noose. The noose was put over the tonsil after the hook, which was continued to the charge of an assistant, and the noose was pushed over the tonsil so as to embrace it completely.

3. The surgeon now drew the ligature strongly towards him, and pushed forward the *entrouvert*, so as to produce the requisite constriction of the tonsil. In general the ligature was not made very tight the first day.

4. When the necessary constriction had been made, the double hook was withdrawn, and the ligature twisted round the tonsil as the twisted end of the double hook.

the best English surgeons; but several cases have been proposed, as, for instance, the tripod elevator; and another invented by J. L. Petit, and afterward improved by M. Louis.

Before beginning the description of the operation, I think it highly proper to remind the reader of what has been so fully described upon the same point, *namely*, of that property by which the water is of pressure of the brain, which pressure must also gradually increase, and which pressure, as the brain is displaced and visible, is the reason for employing the trephine, or, in other words, for removing the skull. There are very few exceptions to this remark. It may, indeed, be said, and then proceed to show away the bony edges around some fungus or some tumor which grows from the dura mater, and under these may certainly be occasioned an absorption of the part of the skull immediately over them.—(*See Davis's Memoirs*). It may also be maintained proper to saw out diseased portions of the skull, though it must be confessed, that in general their absorption should be left to time and nature. Some operations should always be reserved, and, perhaps, if the depressed portion of bone be situated in a wound of the scalp, a mind to raise it with the elevator will be proper, even though urgent symptoms of pressure may exist. In such a case, Sir A. Cooper sanctions the application of the trephine (*Lectures*, vol. 1, p. 241); but it is contrary to the principle which I conceive ought generally here to be our guide.

It is true, that suppuration of the dura mater may follow in such a case; but I do not believe that trephining would tend to prevent it, or, in fact, to prevent it from occurring in antiphlogistic measures; and thus we should only proceed to relieve bone, when the symptoms indicate the enlargement of matter under it, or, in other words, effects from the enlargement of a depression that is the first instance, perhaps, produced in antiphlogistic measures. On this point, however, I deem it but to mention, that Mr. Leslie coincides with Sir Astley Cooper, and lays down the following general rule: that if the depression be supposed to be consequence of a wound of the scalp, let the surgeon apply antiphlogistics, and afterwards decompress; but if there be a depression without a wound of the scalp, it is consequence of the accident, let him not make such a wound by an operation.—(*See Med. Chir. Trans.* vol. 14, p. 403.)

In the records of surgery, innumerable facts may be collected, where the patient and judicious employment of the trephine has effected wonderful cures, and been the only thing by which the patient's life could possibly have been saved. The benefit which the operation brings about is also sometimes so sudden and astonishing, that in no instance does the intervention of the trephine not display itself to greater advantage. The immediate restoration of sight by the depression or extraction of an opaque substance from the eye, is not less wonderful and striking than the instantaneous communication of the intellectual faculties, and of the powers of speech, of feeling, &c., together with voluntary motion, to a person lying in an apparently lifeless state from an injury of the head. The utility of the trephine is occasionally manifested even in this degree. In the valuable essay of Mr. Abernethy on injuries of the head, a case may be seen in which the patient, who had been in a condition almost bordering on senseless, rose up and spoke the instant the extravasated blood was removed from the surface of the brain. And among the wounded at the battle of Waterloo, there was a soldier of the 44th regiment, whose case if of equal interest. He had been struck by a musket-ball on the right parietal bone, which was exposed, but had no appearance of being fractured. At, however, the symptoms of compression were urgent, and the patient was in a state of insensibility. I succeeded it, right to apply the trephine on the part on which the violence had acted. I had not saved long before the cerebral table came away in the hollow of the trephine, leaving the inner table behind, which was not only unfractured, but driven at one point more than half an inch into the meninges and substance of the brain. No sooner were the fragments taken out with a pencil, except, than the man instantly set up in his bed, looked around, and began to speak with me almost rapturously. It is a most extraordinary fact, that this patient got up and dressed himself the same day, without leaving the medical officers, and never had a

bad symptom afterward. Immediately the operation was finished the temporal arteries were exposed, and some purgative medicines exhibited.

Mr. Bristle has seen a case in which there was a fracture with distinct depression of the inner table, with there was a simple fracture, which was easily perceptible, and that without the smallest depression of the water table. He also adverts to the necessity of the trephine, in which there were extensive fractures of the inner table, although the outer was not fractured, and, in fact, not fractured, as stated by Pott, in which, while the outer table was under the hammer, the inner table was broken into splinters, some of which were actually driven into the substance of the brain. As a further proof of the necessity of the trephine, it is mentioned, that the outer table is always broken in a greater extent than the inner one; and the actual depression greater than would appear from the same inspection of the external fracture. These arguments are not disputed in the greater elasticity of the outer table, and greater brittleness of the inner.—(*Med. et Chir. Trans.* vol. 14, p. 200.)

In a case of fracture of the dura mater, with running hole, mentioned by Schneider, the trephine was applied eleven times in less than 24 hours, and the operation used to cause no little indisposition, and the patient hardly ever required to go to bed at night, but on one occasion actually went to bed, and was able to perform his duty.—(*Wandelaar's*, vol. 1, p. 46.)

Let not the young surgeon, however, learn from a few dazzling examples of success, as thousands are able to perform the operation, for it should seem to be a mistake. It is the most painful operation, and when the symptoms themselves show that a dangerous degree of pressure on the brain exists, I consider an unfortunate example, in which the late Mr. Thompson, of St. Bartholomew's, a physician, ventured to saw on a portion of the frontal bone in a young, well-constituted man in the parietal; the patient was seized with convulsions of the face, mouth, and part of the spine, and died in a few days. Two analogous cases of fracture of the bone, with similar fatal results, are also mentioned by Mr. Keble.—(*See Med. Chir. Trans.* vol. 14, p. 201.) That the trephine is not a cure, some risk of a subsequent operation, and absorption of the dura mater, and growth of the bone, is now a fact universally admitted. We may therefore conclude that the operation is not used except from danger; and is, in fact, a most useful one to be resorted to without deep consideration. "Omnis laesio cerebri est species of insanity, and total loss of intellect, without doubt, is the result."—(*Calverley's*, *Med. Chir. Review*, Nov. 1, p. 135.)

In cases of injuries of the head, the organ is exposed in a great measure, except for the purpose of relieving the brain from pressure. Such pressure may be caused by a depressed portion of the cranium, or it may be produced by an extravasation of blood, or the enlargement of matter, between the skull and the dura mater. The chief danger of compression, when the accident is not directly or soon freed from the inflammation and morbid state of the brain, depends upon the consequent inflammation of this organ, and therefore cannot be likely to be benefited by trephining. If the operation becomes proper in such a case, it is when the disease has formed under the meninges, and when the enlarged matter itself grows and is confined by a pressure on the brain. This state of things, however, cannot occur on all after the inflammation of the brain, and its symptoms have prevailed a certain time, as it is always accompanied with a disturbance of the performance, and a puffiness of the face; so that there is a removal of the latter part considered that the disease, the type of convulsions and other symptoms, is a necessary consequence and has itself been removed. The patient has also had much previous convulsions, and, after the operation, the whole head, and the face, and generally the body, is in a morbid state. When the matter is forming between the meninges, and, as soon as it is formed, the pressure is a morbid state, and paralytic symptoms soon ensue. There is the tendency for the present application of the trephine is very great, and the patient's only chance of living is almost entirely connected with the knowledge of the performance of the operation. This important case has been particularly well spent in the writings of Mr. Pott.

In the article *Head, Injury of*, I have laid down the most remarkable symptoms of contusion and compression of the brain, a subject which every surgeon should study with careful attention before he even pretends to explore the brain. The symptoms these accidents are extremely difficult to be discriminated; sometimes they exist together in the same individual, a compression which is probably self-limiting; and, in every instance, where the symptoms are those of contusion, not compression, as far from being transient, would be a step of all others the most likely to do harm, by increasing the irritation and inflammation of the brain, and its membranes. A fall upon the back or upon the head produces a direct compression of the brain, and the shock and being entirely weakened by the excitation of any violent action circulate in the more dangerous. When a person comes into a room with a terrible fall, and is found on his head, his back, his buttocks, the knees, or even the sides of the feet, when he has been severely deprived of his senses, and then by degrees recovers them and seems to himself well; the fact of his having suffered compression of the brain is clear and indisputable. Consciousness may likewise return again, though in a slighter degree, when the patient has been only struck by the fall, and experienced a concussion of spirit. But a multitude of degrees among this field emanate from that which reflects the substance of the brain is unconsciously disorganized, so that there is not the possibility of recovery.

The symptoms of compression of the brain are attended with coma, and the compression of the organ by its membranes is also accompanied with tetanic contractions. Every sign is the symptom to become, whether the symptoms denote either from either the nature of these accidents.

Here, it is to be noted, I have laid down the symptoms of the brain, already made in the above-mentioned article. And there is one criterion of such importance, that it may prove an insurmountable hindrance, and, indeed, prevent the successful collection of its signs, and to interfere with the shock and the whole part of surgery. The first symptom I shall mention is that, notwithstanding it has been already noted elsewhere, in the patient has been knocked down and passed directly by the blow, and receives it a side of sensibility, these primary symptoms are insensible to the operation. On the contrary, when the coma and loss of sense do not take place till an hour or two after the blow, they are to be regarded as a variation.

The shock given to the brain by compression, and the every other insensible communication, continue to dissipate until it ceases altogether. It is at the very time of the blow, that the shock is not less, doubtless enough to produce bleeding symptoms, such symptoms will not afford room on when their cause is weakened. Hence the reason why compression can be discriminated from contusion of the brain, when there has been an interval of time between the receipt of the blow and the occurrence of the symptoms. But the direction of the symptoms into primary and secondary must be made when contusions and extrusions arise together.

Having made these few remarks on compression and compression of the brain, matters which should be carefully before I entered into a description of the compression of the brain, I shall next present some observations relative to contusions and fractures of the skull, some of which the most extensive symptoms have been explained. It is true, that I have in many places been *Head, Injury of*, considered the subject; but it may be better to present certain points here, because they have such immediate connection with the application of the trephine.

Contusion of the head not infrequently occasions a small kind of tumor, which is not in the center, but hard and resting at the circumference, especially when the violence has been moderate. Now the case with which the tumor or seat of the contusion is that which of being depressed, while the surrounding tissue, being hard and elevated, is extremely apt to give rise to the belief, that a fracture may possibly have happened. The true nature of this accident was first clearly explained by J. J. Petit, and since his time, the proper caution not to fall into a mistake respecting it have been laid down by the practice of surgical writers.

Often nothing is more obscure, than the diagnosis, features of the cranium: their nature, indeed can only be made out with certainty when they can be felt by touch. Thus a fracture of the skull, attended with a wound of the adjacent tissues of the lower, shows itself in the form of a linear mark or low ridge and extensive, and taking various directions. The accident may also be known by the touch even when the soft parts appear entire, particularly if the fracture is accompanied with splinters, or the edges of the fissure are mutually separated. When there are many splinters, entirely detached, a trephine will likewise serve to explain the nature of the accident; but, be assisted by these symptoms, reported to him by the sight, the hearing, or the touch, the practitioner must not at once offer a decided opinion as to whether a fracture exists or not.

In order to procure more positive information, would it be right and judicious to make several incisions and remove the bone? But here the patient would be endangered in the very commencement of the procedure; for how could he be able to judge where the knife should be applied? Why also should he resort to a useless and painful operation, when to say the least of it would only render the patient's case more distant?

The symptoms indicating compression of the brain can alone justify an examination of the fracture. These symptoms also must be upon and alarming, for when they prevail to a slight degree, bleeding and evacuation prove more benefit than any operation on the skull; and consequently all examination of the part supposed to be broken must be unnecessary.

Even when the cranium has been divided, so that the sight can carry the information respecting the extent of contusion in the brain, care must be taken not to be deceived by a surface, or by the groove of a vessel. In cases of skull, a modern surgical author advised us to scrape the inside of the bone, and he tells us, that if after the removal of the external scale the fissure yet appear, and a fissure of blood be seen at its outer part, no dissection of it being it real is not. As, however, seeking this examination can numerous purposes, except to a view to determine the place where the trephine should be applied, I cannot recommend the plan, except where the symptoms are such as to render this information desirable. On the contrary, it appears to me, that all examinations of the bone, made otherwise than more curiosity, and without any true surgical object, should be deprecated as rash and harmful.

The danger of fractures of the skull does not depend upon the simple solution of continuity; it being altogether a relation to the compression and compression of the brain, with which the injury of the bone may be compared. The pressure caused by depressed splinters of bone is less alarming, inasmuch as the cause of the compression is easy of removal. The pressure of compressed fluid is far more serious, as consequence of the difficulty of ascending positively its existence and precise situation.

It is not in vain that between the skull and the dura mater, which is detached from the bone. More frequently it occurs either between the dura mater and crura mater, or in the substance of the brain, or the dura mater. The quantity of extravasated fluid is generally less in these extravasations which are situated between the dura mater and the skull, unless they be in the course of the middle meningeal artery, when they are frequently very copious. The extravasations which are formed in the substance of the brain itself are not only more considerable, but also, as they mostly depend upon compression, are more alarming, than effusions on the surface of the dura mater. It is indeed extremely difficult, if not impossible, to ascertain the situation of the extravasated fluid. In such cases, the trephine is chosen of no use, while contusion, when so violent as to produce internal extravasation, is invariably fatal. In extravasations between the dura mater and the skull, which are about the half of the case of the kind which are very soon admitted relief, when the effusion which lies under a part of the skull, accessible to the trephine, the extravasated fluid is generally, except in the instance just now specified, easily to evacuate. The danger, however, is not the least but to involve deep of fluid can sometimes enough to produce a fatal compression.

When the extravasation has happened in the substance of the brain, the compression is far more potent; in short, it may be said to press, with very few exceptions, certainly mortal.

The language, the degree of which increase from more depression into the most perfect coma; and the paralysis of the opposite side of the body to the spot of the extravasation; are the most common symptoms of this accident. Having explained elsewhere (see *Med. Legalis*, &c.) some other symptoms, such as strabismus, compression of the pupil, &c., which usually indicate pressure on the brain, it is unnecessary here to dwell upon them. The subsequent increase of the coma and paralytic affections, and the gradual diminution of their intensity, serve to render these symptoms distinguishable from others which are suddenly brought on by concussion. But there are instances, as every man of experience knows, in which continued rigidity, the fixed pupils, and profuse an extravasation of blood. In this circumstance, it is obvious that the symptoms of compression too blended with those of concussion. The symptoms proceeding from the latter cause always diminish in proportion to the time which has elapsed from the moment of the injury: while those of compression, instead, and, on the contrary, increase progressively, in proportion as the quantity of extravasated fluid becomes more considerable. Notwithstanding these distinctions, however, it need be acknowledged, that there are many cases in which the surgeon is obliged to remain in doubt with regard to the particular cause of the symptoms. This uncertainty is the more embarrassing, because the operation of the trepan is necessary in cases of extravasation, but useless in those of concussion. Even when extravasation is known to exist, the practitioner requires more information; for he ought to know the precise situation of the effused fluid. It is true, indeed, that paralysis of one side of the body generally indicates the pressure to be upon the opposite hemisphere of the brain. But this rule would venture to follow the position adopted by Van Swieten, and apply to the unoppressed side of the solid brain contents of the trepan? Possibly, not one of these could fall on the situation of the extravasated fluid. When the skull is broken, the extravasation is seldom always on the same side as the fracture. When it is, the effect of concussion, or when the location of contusion in the skull is what is termed a counterblow, the effusion is generally on the side of the head most remote from the blow. If the pressure is caused by a detachment of the internal table of the skull, the nature of the case cannot be ascertained before the operation of the trepan has been performed on the part of the skull upon which the violence has acted. When these facts are ascertained, one depending upon a fracture, and another immediately under it, between the dura mater and the skull, the case arising from contusion, and situated at some point directly opposite, either between the dura mater and the internal table, or within the substance of the brain itself, paralysis may occur on the same side as the fracture; and hence it may be inferred, that the pulse does not always take place on the side opposite to the extravasation. But, say Blackman, an extravasation of the brain quickly proves that the case does not derive from the cerebral table. This extravasation produced by concussion being almost invariably more considerable than that caused by a fracture, accounts for the extension of the pulse to the same side of the body. Sometimes the side which is not paralytic is affected with convulsions, the pulse is full and hard, and the respiration stertorous; in short, the symptoms are analogous to those caused by apoplexy.

The following observations and advice fully accord with the doctrine which I have always advocated in my writings upon this part of surgery, and they also agree with the position which was so successfully adopted by an illustrious man of the school of the Altkönig, recorded in the *Annals of Wurzburg*, as already mentioned; it is therefore with great pleasure that I quote the authority of Mr. Brodie on a point about which practitioners have been so much perplexed: "Blood corpus Mr. Brodie is seldom poured out in any considerable quantity between the dura mater and the bone, except in consequence of a laceration of the middle meningeal artery, or one of its principal branches, and it is very rare in the accident

to occur, except as a consequence of fracture. If, therefore, we find the patient lying in a state of stupor, and on examining the head we discover a fracture with a violent depression, extending to the division of the middle meningeal artery, although the existence of an extravasation on the surface of the dura mater is not thereby related to an absolute certainty, it is rendered highly probable, and the surgeon, under these circumstances, would neglect his duty if he refused to apply the trephine; and others as prudent as he, however, yet if there is other evidence of the injury having fallen on that part of the cranium nearest the middle meningeal artery is situated, the use of the trepan may be resorted to on speculation, rather than that the patient should be left in his present state, although being made for his preservation. I cannot, indeed, adduce any particular experience of the use of trepan in cases of what is here recommended; but I caution that the instances which have been recorded, in which the middle meningeal artery has been ruptured without any fracture of the bone, and the brain has then there sustained a fracture at the same time if the skull, while there is some of the same side, evidently justify such an experiment in desperate cases." (*Précis de Méd. Chir. Trans.*, vol. II, p. 265.)

With the foregoing exception, in which, indeed, a ground for suspecting the seat of the effusion must rest upon the knowledge of the point upon which the violence has operated, the craniotomy is recommended for the treatment of concussion. But, *legibus*, &c., in all that can be done with every thing is uncertain, and the operation of the trepan is, in all that can be done, it is true, in some instances where the effusion has taken place in the substance of the brain, so that it cannot possibly be evaded. The trepan then is indicated very soon, then, in an extravasation between the dura mater and the bone, the fracture being situated at a part of the skull accessible to instruments, and not at the base. Why not, then, have done upon the doubtful fracture, where we find this between the dura mater and the bone? I believe that the operation should be resorted to in a small number of cases, in which not only the nature and situation of the pressure are known, or may be suspected on the ground above explained, but in which the symptoms arising from this state are urgent and dangerous, and the pressure can be removed by no other means.

Death in the last years of his practice indicated the operation of the trepan altogether, as it seemed of the little use, having become useless. Progress of the present day trephine with more caution and discrimination, and sometimes with such success.

When the case is a simple fracture, the trepan ought to be applied upon the solution of continuity, if the symptoms indicate a dangerous degree of pressure on the brain.

When the detached portions of bone are displaced, so as to compress the brain, the operation is still necessary if they cannot be elevated by other means. The likelihood, however, that a positive benefit will be derived is not frequent, either because it is difficult to judge of the existence and situation of the pressure, or because extravasated blood cannot escape through the sponginess of the fragments when they are in a splintered fracture. Such facility is not to be expected when one of the portions of bone has been so badly displaced, so that it can be removed, having an opening equivalent to what would be produced by an operation of the trepan.

When the operation is discontinued, the skull should be shaved; indeed, this is often done immediately that surgery is called, in order that it may be a better opportunity of seeing what parts of the skull have been struck; for it is in such situations that it has most reason to apprehend fracture of the bone, or extravasation beneath it. If, however, the evidence has indicated a large wound or laceration of the scalp, the practitioner, knowing where the trepan has been applied, is frequently content with having a hole of the hair shaved off the place surrounding the injury. All that need be said on this subject is, that it is always better to have enough of the hair taken away, so that the surgeon can unobscuredly see the spot of extravasation, the scalp freely, and doing whatever may be necessary. The use of a little hair is of very little consequence, while the concealment of the seat of a depressed

nature, or extravasation, might lead to fatal consequences.

When the propriety and necessity of trephining are fully indicated, provided the wound or incision of the scalp should not have exposed a sufficient surface of the bone for the application of the crown of the trephine, an adequate dilation of such wound ought necessarily to be made. If, in the situation of the bone, there should only be a commotion, or a laceration, unattended with any wound, a division of this part of the scalp is to be made by carrying the knife quite down to the bone. In those cases in which the swelling occasioned by the violence is considerable, and attended with the presence of a cystic, or an abscess in other instances, in which there is only a commotion, under which a fracture has displaced pieces of bone may be felt; the scalp must be divided in the same manner, only with greater caution, lest the point of the knife should penetrate itself through the fracture, and be pushed to the dura mater and brain.

Authors recommend the shape of the incision to be different, according to the kind of fracture and the parts of the head on which the violence has operated. When the whole extent of the injury can be brought into view, by means of an incision having the form of the letter Y, the incision should be content with such a division, but if this be not sufficient, he may give it a crucial shape. When the trephine is to be applied to the squamous part of the trepan bone, we are recommended to make the incision as thick as possible in the shape of the letter Y, the branches of which are to be straight, and the angle downwards; in order that as late as possible of the temporal vessels may be cut, and that the division of its fibres may be avoided as far as it is in our power.

Having divided the scalp, the next object is to reflect it, but no man would be warranted in cutting any part of it away, although such practice is advised by Ford. The purpose of the operation is not to require any removal of this kind; and the method would leave a wound which would be long in healing, and which would never escape from disfigurement. In short, the reflected flap of the scalp is capable of adhering to the parts on which they are laid after the operation, and consequently ought never to be wantonly cut away.

The scalp being reflected, nature next advises us to scrape away the perforation, either with the hand or the raspatory. Perhaps this sensitive way be considered as one which does neither much harm nor much good. The design is to facilitate the application of the trephine to the bone. However, the touch of a proper instrument, in good order, will not be impeded by the slender pericranium; and scraping this sensitive away from parts of the skull which are not to be removed may conduce to calcification.

Sometimes the bleeding from branches of the temporal or occipital artery is so copious, that the best cause be very conveniently performed before the hemorrhage is stopped. If it be prudent to wait a little, and the case (as it generally does) should be likely to be benefited by the extraction of blood, it is no well when the bleeding ceases for a certain time. The surgeon may then put direct an assistant to put the end of one of his fingers on the mouth of the vessel and prevent its operation. In some cases, the bleeding might be so troublesome, that it would be better to cut the artery at once.

All parts of the cranium do not admit of being trephined with equal convenience and safety. It has usually been set down by surgical authors, that the trephine cannot be applied below the transverse ridge of the os occipitis. There the same rules, however, which prove that such an operation may be safely done, and that we ought not, in urgent circumstances, to be afraid of dividing the trephine and compressing arteries, in order to be enabled to apply the trephine to the bone.—(See *Mitchell's Case* in *Med. Clin. Trans.* vol. 2, p. 194, &c.)

The situation of writers who limit the application of the trephine to the frontal sinuses, is consequently of the intermediate duty of these crania, and the application of trepanning to the frontal sinuses. However, Lattre has deviated from this precept in several instances, and his practice confirms the statement of Mr. C. Bell, that by opening the frontal sinus with a large trephine, and then using a small one, the internal junction of this

cavity may be trephined with perfect safety, and no risk of injuring the dura mater with the saw.—(See *Lattre's Méth. de Chir. Opér. Militaire*, t. 2, p. 136—137, &c.)

Written also caution us not to apply the trephine to the superior inferior angle of the parietal bone, in consequence of the middle artery of the dura mater lying under it, generally in a groove of the bone, and occasionally in a canal in its very substance. In the latter circumstance, the position of the parietal bone could not possibly be taken away, without wounding the vessel. However notwithstanding this advice, which has been unthinkingly handed down by one master to another, from generation to generation, I very much question the existence of the doctrine. We undoubtedly rapidly affirm trephining this part of the cranium, we can probably do so. But the cases demanding this operation are always so urgent, that the patient's sole chance of existence depends on their quick removal. Hence, were these pressure on the bone, either from a degenerated portion of bone, from blood, or matter, and such pressure could not be removed without trephining the superior inferior angle of the parietal bone, what operator would be afraid of doing so? Besides, the fear of the hemorrhage has been very undervalued; for the judgment of the artery in a deep fissure of skull, which authors have proved not to be rendering the suppression of the hemorrhage more difficult, is a mere visionary idea, as it is well known that a little plug of fat, pushed into the orbit of a vessel so situated, will at once stop the bleeding, with as much certainty and ease as can possibly be imagined.

The foregoing suggestion was made in the early editions of my works, and I now see the safety of the practice has been confirmed. "I have also applied the trepan upon Lattre's over the track of the opthalmic artery, at the inferior anterior angle of the parietal bone. The artery was divided, but I stopped the hemorrhage almost immediately, by applying an iron probe not far."—(See *de Chir. Opér. Militaire*, t. 2, p. 136.)

Writers, until very lately, also cautioned us from trephining over any of the sinuses, and especially over the sagittal sinus, because which the longitudinal sinus is situated. The fear of the dura mater being injured, and of the vessel being wounded, was the reason for this advice. With regard to the sinuses in general, the trephine may be applied as high as well as in any other part; and as for the sagittal sinus, many facts confirm the propriety of not being deterred even by its though situated immediately over the occipital sinus. It is to be remembered, now, that the dura mater is a mass of extravasated blood, and matter beneath the cranium, is attracted by the attraction of such fluids from the lower table.

By means of a perforation practised over the sagittal sinus, Garretson successfully elevated a portion of bone which pressed upon the longitudinal sinus, and made the patient quite conscious. The depressed piece of the parietal could not have been so advantageously raised, had the trepan been applied in any other situation. But a still stronger argument is in favor of this practice, when the case at all requires it, is the fact that wounds of the longitudinal sinus, and the hemorrhages consequent from them, are not attended with any special danger. Sharp mentions his having twice seen a bleeding of this kind. Another instance is also recorded in Wagner's Cases. A child received a blow on its forehead; the two parietal bones were fractured, and a considerable richness depressed on the dura mater. The child lived a month without any operation being done; but at the end of this time Warner applied the trepan. He found a quantity of blood oozing in with a ray into the longitudinal sinus, but it could not easily be got out; consequently he enlarged with a lance the opening in which the spout was completed. The hemorrhage, which was copious, was easily stopped by the application of a little dry lint, and the child was restored, though it died at the end of two months, after suffering a variety of symptoms which had no connection with the wound of the sinus, the opening of which was ligated. The fourth case, related by Marshall, also proves that wounds of the longitudinal sinus are not fatal. But and Calver from some reported other facts, leading to the same conclusion.—(See *Appl. Chir. Moderne*, p. 1, p. 88, edit. 1786.)

Whenever a depressed fracture can be elevated to its proper level without applying the trephine, and with the mere aid of a pair of forceps or an elevator, trephining should never be performed, unless there be strong reason to apprehend that blood, or matter, lodged on the surface of the dura mater, contributes to the production of the bad symptoms, and constant pressure be discharged.

The scalp having been divided, if necessary, and the trephine being adapted to the surface of the bone, according to the common precepts and practice, the next thing is the application of the known of the trephine.

The trephine is first to make a little incision with the point of the centre pin. For the purpose of marking the place where it will work, when the crown of the trephine is applied in the proper situation, for where such incisions are made, the operator must make a small hole with a perforator, in order to fix the point of the centre-pin, on which the crown of the instrument turns backwards and forwards, as on an axis, during the first stage of the operation. Mr. Denigrey's centre-pin makes a perforation, without need of any particular instrument for the purpose, and in this respect is of advantage.

The point of the centre-pin having been fixed, the trephine is to be turned by regular oscillating motions, alternately to the right and left, which motion is effected by steady pressure and rotations of the operator's hand. The teeth of the saw having made a marked circular groove, in which they can readily work, the trephine becomes steady, and as it would, if not withdrawn or removed, certainly injure the dura mater and brain, by reason of its projecting farther than any other part of the instrument, it would be an expedient to draw it in a woman after a proper circular groove had been formed by the teeth of the saw.

The beginning of the sawing might be executed boldly and quickly, for the operator must be careful of doing mischief. It is necessary, especially, with the view of facilitating the action of the instrument, to clean away the particles of bony matter with a little brush, usually kept for the purpose in every box of trephining instruments. When this has been effected, the action of the cylindrical saw would be very much clogged.

The operator, however, must increase his caution, when the sawing has made greater progress; for were he to be too bold, he might sometimes increase the massiveness of the brain with the teeth of the instrument, particularly in the thickness of the cranium, as when to induce variety, but in different parts of the same head and in different subjects. Let the surgeon, therefore, never forget to examine frequently, with the point of a quill, whether any part of the bony plate is cut through or nearly so; for when this is the case, the instrument must only be worked in with a try or to make pressure upon, and cut, the part of the circle which yet remains to be divided. In some few cases, it is said, that the surgeon can distinctly feel when the teeth of the saw reach the dura or pericranial membrane between the two tables of the cranium, and some writers have merely directed us to run with hollow till the sensation of the membrane is communicated to our hand, and fingers. However, I believe, this possibility of discerning the arrival of the teeth of the saw at the dura is an uncertainty and an fallaciousness, that it should never be expected or relied on. Nor ought the surgeon to saw with uncertainty, force and rapidly, till he sees the teeth of the trephine clearly, which appearance has been apt taken as another evidence of their having reached the dura. I have already stated, that a great many skulls have bony are some between several parts of the trephine. This is particularly often the case in the parietals.

A patient man will always prefer cutting a little lower for the purpose of leaving more of the bony substance, making the circular piece of bone, in making any hazard of injuring the dura mater by having too deeply. After a certain time, therefore, it is better to lay down the trephine, and endeavor to elevate the portion of bone, with the aid of a pair of forceps constructed for the purpose, and kept in most cases of trephining instruments, or else by means of an elevator, which is still more calculated for the purpose.

When the circular piece of bone has been taken out,

and the edges of the perforations are scraped and polished, the irregularities are to be cut off with the trephine itself. When there is extraneous blood so deposited on the opening which has been made, it sometimes spontaneously makes its escape, and if it should not do so, the surgeon must remove it himself. If the perforation of the skull should not suffice by letting out the blood, so much more of the trephine might be removed till the trephine be so constructed that might; there being no comparison between the danger of repeating the application of the instrument, and that of leaving a quantity of undischarged, coagulating blood on the surface of the brain. Certainly, many facts on record assure, that the dura mater has very extensively recovered without dangerous consequences. Passing into a white cerebral tumor (tubercle), in consequence of a blow on the head. Every thing is similar here, and Marsden makes mention of a woman who had lost the upper part of the os frontis, both the parietal bones, and a large portion of the occipital, all of which had come away in the same time; yet she recovered. Various, however, who seems also to relate this curious case, attributes the exhibition to not being quite so common.

I am of opinion, notwithstanding these facts, that exposing a large part of the dura mater with its capsule is by no means an operating clamp from which danger. And what I consider the chief danger, is my having known instances, in which persons who had been much injured by a blow to the head, and for the sake of violent pains in the head, as, and in consequence of the operation. I write this observation, with anxiety of the successful nature of the practice advocated by Dehaenckx. (Wunderk. 8, 1, p. 434.)

However, I perfectly coincide with Wilson who directs the removal of as much bone as is necessary to enable him to be able to remove the whole of the pressure from the surface of the dura mater.

The application of the trephine, in cases of large extrusions, must in particular be made several times, when the situation of the fluid does not allow it to escape. But in this circumstance, Dehaenckx says, that we should not make numerous perforations at along the extent of the extravasation, but only a counter-opening, as is done on the left side. This author expresses his surprise at there not being recorded many examples of counter-opening even in the cranium, since anatomy demonstrates their utility. I cannot help remarking on this part of the paper, that was very obvious objection to making repeated trephines in the cranium, is the impossibility of knowing, with certainty, whether blood lies under any particular part of the skull; whereas, in disease of the soft parts, the surgeon feels the fluctuation of the matter, and knows that his counter-opening will be made in the cavity containing it. One may sometimes have occasion to make so, that our intention is to discharge blood extravasated beneath the skull, when the flow has happened near a point, in which the dura mater continues adhered to a single opening, made only on one side of the artery, might not only vent but a part of the extravasation.

When the trephine is applied, on account of a fracture with depression. Mr. Brooke considers the removal of a small portion of bone as generally sufficient; so when the case is an extrusion of blood on the surface of the dura mater, he recommends a large removal of the skull. He was led to adopt this rule by having seen a case, in which, after two triangular pieces of bone had been taken away with a straight saw, and a large quantity of blood discharged, to the great relief of the patient, supuration followed took place on the surface of the dura mater, notwithstanding the wound had been repaired by the extravasation from the bone. The matter was followed by the surrounding tissue, from exuding by the aperture already made, and though another portion of bone was removed, the patient was too late to save the man's life.—See Med. Obs. Trans. vol. 24, p. 267.) Whether so extensive removal of the cranium ought to be usually made in anticipation of supuration of the dura mater in such a case? Whether such a removal might not rather tend to make the cerebral matter more exposed, and whether the position which Mr. Brooke admits adapted might not have been the best, though, in the instance brought forward, unsuccessful? are questions

Work, in which the most skillful surgeons may be little different of opinion. As my principles lead me to disapprove of the old method of opening for the purpose of preventing inflammation and suppuration of the dura mater, they would induce me to be content with rigorous antiseptic treatment, and discharging the residual fluids as soon as the effects of its pressure begins to show themselves.

If we should not find blood lodged under the arachnoid, but the dura mater should seem elevated, brown, dark-colored, having a prominent fluctuating tumour outside, it may be cautiously opened with a bistouri in the middle, with a view of letting out any collection of blood underneath. In the article *Head, Injuries of*, I have stated the result of Mr. Althaus's experience, in regard to the operation of opening the dura mater. This gentleman would use the method very effectively discharged all the blood, but only the worse part of it. The evacuation of any of the compressing fluid must, however, be desirable; and if the surgeon cannot do more, yet he has fulfilled his professional duty.

Although Mr. Brodie admits that wounds of the dura mater are attended with great danger, he expresses of the practice here recommended (see *Med. Chir. Transactions*, vol. 14, p. 287), and supports his opinion by reference to an interesting case under the line Mr. Cheever. This gentleman was called to a patient, a year and a half old, which had received a severe blow on the head, and lay insensible and convulsed. There was no wound of the scalp, but the fontanel appeared somewhat elevated. It was therefore opened by a trephine, and raised some to remove the congested dura mater; beneath which the purple colour of extravasated blood was plainly discernible. A puncture having been made with a lancet, three or four ounces of blood issued out with considerable force; the symptoms were satisfactorily relieved, and the child recovered.—See *Med. Phys. Journal*, vol. 5, p. 265. An analogous foregoing an equally interesting proof of the practice here advised, is also published by Mr. Brodie from the practice of my friend and neighbour, Mr. Ellis.

The utility of trephining is not limited to discharging extravasated blood or matter lodged underneath the skull. This operation frequently enables us to remove depressed portions of bone. The latter object can often be accomplished by merely making one perforation. Sometimes several perforations are requisite to be made near each other. Artists were wise, that it may also become necessary to remove the surrounding portions of bone with a pair of cutting forceps. The supposed part may then be firmly raised by means of an elevator. Occasionally, indeed, I may say, very often, the best practice is to remove the depressed portion entirely, takes its total assumption from the rest of the skull may be accomplished by raising across the base of the depressed piece.

According to some writers, if, after dressing the dura mater, the surface of the brain appears smooth and fleshy, with a fluctuation, we may conclude there is all disease in its substance, and these authors, more extensive with their pen, it is to be bled, than with their scalpel, mention the method of carrying the point of the bistoury to the depth of an inch, if circumstances render as deep a puncture necessary. "But," says Richardson, "experience forbids us to go farther. Cutting the surface of the brain causes no pain, and it produces less danger than one might apprehend; experience and observation prove its opposition to phlogistic theories; that the essential parts of this organ are situated some six lines, and that its surface may be removed without danger or pain."—(*Neurolog. Jour.* 1, 2, p. 201, et 2.)

A case, in which Daguerre, painted a history to the depth of more than an inch into the brain, and that he set on fire and a half of pure, is recorded in a valuable periodical work.—(*Sci. Jour. of Foreign Med.* vol. 18, p. 286.) Some temporary mechanical relief of the chest had a fatal termination.

After the operation of trephining, the divided scalp it is to be guided as nearly as possible in its natural situation, and tightly dressed with a simple powder of any essence in astringent character. In applying the dressing, the surgeon should invariably keep in view these objects: namely, to let whatever is put on the wound be as light as possible, not apt to stick to the wound, and of a nature to keep without irritating.

All assistants are to be strictly avoided, nor will any bandage be better than an ordinary night cap of sufficient size to be put on with facility. It may be secured with bits of tape, which not to be tied under the jaw.

The practitioner should not lose recollection that he has done all that he ought to do. Let him remember the urgent necessity of keeping off, or discharging, the inflammation of the dura mater and brain, which is still to be feared. Let him bleed the patient largely and repeatedly; exhibit saline purges, diuretics, and anasthetics; and if the symptoms continue, let him apply a blister to some part of the head. I shall avoid, however, any repetitions on this subject, by referring to *Head, Injuries of*.

The aperture in the skull usually becomes closed with soft granulations, which slowly acquire a hard consistence. While the cranium is wet, it should be protected from external injury with a thin piece of bone or metal. Excitations from the margin of the perforation sometimes retard the healing of the wound; but even that the practice of dressing with drying effluvia application has been exposed, and the removal of any part of the scalp is continued by all the best surgeons, these unpleasant consequences are avoided much less frequent than in former days.

The reader may find an account of the operation of trephining or trepanning in every system of surgery; but he should particularly consult the writings of Sharp, Le Moine, Brown, Blandin, Pott, Schaeffer, Schaeffer, Hirsch, Denon, Abernethy, Denon, Callender, Richardson, C. Bell, and several parts of the *Med. et Chir. de Chirac*. Also, *Le Cerebro et les Joints de la Base*, by M. Ch. Pons, vol. 14.

This article on the trephine contains perhaps the most valuable practical information any where to be found in the language. The excellent diagrams between construction and consequences, and the valuable arguments against the indiscriminate use of the trephine, and in favour of large and repeated evacuations, cannot be too frequently known nor too highly estimated, especially by the young surgeon.

It is a high source of gratification to be able to record, that in this country, the trephine is now much more seldom used than formerly. But a few years ago, for a man being strangled by a horse or a fall, in any considerable extent, almost any neighbouring physician would apply the trephine without hesitation, and the facility with which this operation can be performed, offers no small temptation to the more careless, especially as there is seldom any risk of life, and always a gain in reputation among the multitude. It is now very generally viewed as it ought to be, as a desperate remedy, known the symptoms of compression by depressed bone, or extravasated blood, not altogether unimpaired, and a consultation with the best surgeons is always desired.

I have seen several persons, who would have formerly been trepanned, without even a "trial by jury," recovered from coma, paralysis, and convulsions, partly attributable to compression on the brain, by very large and copious bleedings, aided by cathartics and stimulating tonics and stimulants to the circulation.

Still, however, there will be a sufficiency of instances, frequently requiring the use of the trephine, to render it necessary that every practitioner should be conversant with the instrument, and all the circumstances connected with its use. Indeed, some of the most deplorable cases in which surgical assistance is ever rendered, are occasionally met with under the example in which the trephine becomes indispensable.

In the year 1819, I attended Dr. Henry Wm. Dracut, then a practitioner in the city of Baltimore, in the performance of this operation on a woman who had received several blows on the head with an axe, from a brutal husband. We could discover no depression of bone, and yet the signs, stertor, anisoplegia, and other evidences of compression, rendered us all perplexed, and we the third day after the violence, we determined to apply the trephine, being convinced by previous reasoning in our opinion, that there must be extensive extravasation of blood beneath the cranium. On removing the circular piece of bone, with the largest crown of the instrument, a coagulum was found extending over the left hemisphere of the brain, which we the dura mater. This being removed, and only a dissection of the arachnoid covering the cere-

along with it in the same improper direction. Long-established purulent discharges from the lachrymiferous glands likewise speed the shape and consistency of the distichs of the eyelid, and therefore not infrequently occasion trichiasis. Scarpa doubts whether a spasmodic contraction of the orbicularis palpebralis muscle can ever be a cause of the disease.

The strabismus which most frequently results from the lachrymiferous glands pointed upon the cornea and while of the eye, as Scarpa observes, may be easily diagnosed. The eye is rendered still greater by the lachrymiferous glands which remain lessening much longer and thicker than those which retain their natural direction. And although the trichiasis be confined to one eye, both the eyes usually suffer from the effects of the disease. Indeed, generally, the eye on the sound side cannot be moved without encountering pain in that which is exposed to the irritation and action of the infected lachrymiferous glands. In almost all cases, both the eyes are very sensitive, and incapable of bearing the light. As, in cases of incomplete trichiasis, the patient retains some little power of opening the eyelids for the purpose of seeing, and thus more frequently towards the internal angle of the eye, the lachrymiferous glands are often included in an inverted position, as first in children a dislocation of the neck and sometimes in an adult produced, which cannot be rectified without difficulty, even after the trichiasis is cured. Otherwise, and children are ignorant of the strabismus arising from the infected lachrymiferous glands, and therefore are constantly rubbing the eyelids, whereby all the ill effects of the complaint are nearly increased.

The cure of the second species of trichiasis, or that which is commonly met with in practice, is accomplished by artificially erecting the eyelid, and fixing it permanently in its natural position, together with the eyelashes which protrude the edge of the eye. According to Professor Scarpa, this indication is perfectly fulfilled by the removal of a piece of the skin close to the edge of the eyelid, of such a breadth and extent that, when the cicatrix is formed, the tarsus and margin of the eyelid may be turned upwards, and sufficiently separated from the eyelid, the cicatrix of the lachrymiferous gland being a point of support fully adequate to keep the points in their natural position and direction. Scarpa believes that very few modern surgeons, with a view to the radical cure of this disease, have pursued any successful effort at plucking out the inverted eyelashes, binding them with birds, and retaining them with sutures of silkworm gut; or in plucking them out, and destroying their roots with caustic; much less in separating the edge of the eyelid along with the hairs, or dividing the orbicularis muscle on the internal surface of the eyelid, under no idea that the disease is sometimes produced by a spasmodic contraction of it.

The following is the mode of proceeding recommended by Scarpa. The patient being seated in a chair, if an adult, or, if a child, laid upon a table, with the head raised, and firmly held by an assistant, who must stand behind the patient, the surgeon is to pass upwards, with the end of a probe, the hairs which excite the eye. Then, with a pair of dissecting forceps, at the ends of his fore-finger and thumb, he should lift up a fold of the skin of the eyelid, taking great care that the place which is taken hold of corresponds exactly to the middle of the whole extent of the eyelid; for sometimes the whole, sometimes a half, and, in other instances, only a third of the extent of the tarsus is inverted. The surgeon, with his left hand, must raise the fold of the skin more or less, according as the relaxation of the integument, and the anteriority of the tarsus, are more or less considerable. The reason of this is evident, viz. the greater the quantity of skin which is raised, the greater is the quantity which will be cut away. Supporting the patient to be an adult, as soon as the fold of skin has been raised to a certain degree, the surgeon must request him to open his eye; and it is then as the tarsus and eyelashes resume their natural place and direction, the portion of skin already raised will be sufficient for the purpose. Whereas integuments are elevated by means of a pair of dissecting forceps, and thus is taken to lay hold of the skin precisely on the middle point of the whole extent of the trichiasis, it necessarily follows, that the consequent removal of the skin will form an oval, and that the greatest width of the wound will correspond exactly, or nearly so, to the middle of the eyelid, and its narrowest parts to the angles, or inner

extremities of the inner. This constitutes very sensibly to make the cicatrix correspond to the natural fold of the eyelid, and under the origin of the disease of an opposite nature to the one about to be removed, to raise the angles of the eye, viz. a turning out of the commissures of the eyelids.—(See Engravings.)

Besides this caution, relative to the situation and degree of the fold of the integument to be cut off, the surgeon must be careful that the division of the skin be made very near the inverted lachrymiferous glands. Were this circumstance neglected, the operation might have the effect of increasing the disease, after the wound is healed, that although the eyelid is straightened, on the whole, from the eyelid to the place of the cicatrix, yet it is not equally so at the space which is between the edge of the eyelid and the cicatrix of the skin. Hence, the lachrymiferous gland, so turned upwards sufficiently to keep the eyelashes from rubbing against the eye.

The surgeon, holding up the fold of skin by means of the forceps in his left hand, is, with a pair of probe-pointed, sharp-pointed scissors, to cut off the whole of the integument being fast upon that one of the blades of the instrument is applied close to the edge of the eyelid. If the eyelid should be affected, the surgeon ought to make immediately be done upon both of them, with such caution, and in such proportion, as the extent of the disease, and the degree of inversion of each eyelid may require.

Scarpa warns surgeons not to employ any means to make the wound, and expresses that it will be sufficient to keep the eyelids as much separated as possible, if the operation has been done on the upper eyelid, or, if on the lower, is to support it against the inferior part of the orbit, by pressing it from below upwards, so as to keep the edges of the wound from becoming apposed. Then the lips of the wound are to be brought exactly together by means of adhesive plaster, which should extend from the superior margin of the orbit to the zygoma; and the maintenance of this state of the wound will be still more securely effected, by placing two compresses, one on the eyelid, and another on the zygoma, together with a bandage. On the other hand, Lamechlock disapproves of the common of sutures, by which he finds that the wound may be both more accurately and expeditiously joined. Indeed, he expresses himself generally in favour of suture, where the wounded part is liable to be disturbed by its natural action of muscles.—(See Engr. C. I. p. 415, &c. 22nd. However, 1818.) Lamechlock, however, takes care to withdraw the ligatures in about twelve, or at most twenty days, before, as their longer continuance would produce suppuration. He is also particularly insistent upon the utility of bringing the edges of the incision together with a suture, and both he and Lamechlock employ Scarpa's mode of which have transverse pieces, calculated to take better hold of the lips of skin to be removed.—(See Engr. C. I. p. 114.)

On taking off the first dressing the third day after the operation, the surgeon, with God, says Scarpa, that the lachrymiferous glands by eye with care, and that the inverted tarsus and eyelashes have resumed their natural position and direction. In the partial or incomplete trichiasis, or that which only occupies a half or a third of the whole length of the tarsus, and in subjects who have had the skin of the eyelids very loose, Scarpa has often found the wound perfectly united on removing the first dressing.

When, however, only a part of the incision has healed, while the rest remains disposed to heal by suppuration and granulation, the surgeon is to cover the wound with a small piece of lint, spread with the aqua-ammoniacæ, and if the sore should become fleshy, it must be occasionally touched with the argentine nitrate, until the cure is finished.

With regard to the first form of this disease, or that in which the eyelashes project against the eyeball, without the natural position of the tarsus being at all altered (a case which is extremely rare), the accomplishment of a cure is very difficult, since, without the pulling out of the hairs, not leaving the situation of their roots, nor means at all to be dependent upon for producing a complete cure of the disorder; and leaving the tarsus out of its natural position would make the patient liable to an irreparable dropping of the tarsus over the cheek, attended with a chronic thickening of the lining of the eyelid. It has only been in young subjects, that Scarpa has ever seen the required and

In a similar way, at the inner angle, without irritating the patient's eyeballs. "The length of which the perpendicular incisions at both angles ought to extend must now be decided upon by the appearance of the part: they must be continued, if necessary, by repeated incisions with the scissors, until that part of the eyelid containing the tarsal cartilage is perfectly free, and is evidently not acted upon by the fibres of the orbicularis muscle." The part included in the incisions is now to be completely removed, and obtained by the dissection of the specimen's left hand against the patient's brow; taken, if any larva is observed to be observed, covering the lid, it is to be divided. "On lifting the eyelid and on the eye, the edge of the tarsus and the hairs will frequently appear in the same situation, in consequence of the relaxation of the ligament which bound them down; but if the tarsal cartilage has become altered in its curvature, this will be immediately perceived: it will then present at its convex edge, and be completely bent at its concavity, more especially in the inner case, where it is now powerfully acted upon by the ciliary muscle. On drawing the patient to raise the lid, he usually attempts it, but the action of the levator, in such cases of various curvatures, causes the cartilage to assume its situation, and on examination the curve will be observed to be so persistently vicious, for about an eighth of an inch at each extremity, and especially at the inner, that it cannot be induced to resume its natural situation. When this is the case, the cartilage is to be divided exactly at the place where it is bent in its length, and in a direction at a right angle with the perpendicular incision, the portion thus cut is only connected with the common fragments of the eyelid, and although the incision scarcely exceeds one, and never two, eighths of an inch, at both extremities, and in general it is only necessary in the inner, a needle the cartilage to remove the altered curvature of the part." The cut proceeding in Mr. GUTHRIE'S operation consists in cutting away a fold of skin from the part of the eyelid between the incisions. Three or four ligatures are then to be introduced, and the divided parts, from which the fold has been removed, are to be brought together by the ligatures, each of which is to be twisted and fastened to the forehead with several short strips of sticking plaster. The Aid of this should be renewed regularly with the finger, and as near as possible to the margin of the eyelid. It may then be taken hold of with four's forceps, the grasping pieces of which are knurled, slightly curved, and bent with a spring. The skin thus taken hold of, which need not be large, may also be cut away with a large pair of curved or straight scissors. The ligatures are first inserted at each angle, and when the viscous substance is considerable, Mr. Guthrie may insert three through the skin, but takes care to separate the natural one include, or to leave just, the outer edge of the margin of the eyelid. The ligatures, thus placed, are to be equally drawn up on the forehead, until the eyelid is completely everted. When they are to be removed in the manner above specified. It is then to be moved down by the first incision, and make the granulating process necessary, the edges are closely finished with the sulphuric acid of copper. The eye and eyelid are now to be carefully cleaned, a piece of lint, moistened with the oleo. tennos, is to be placed upon them; a clean compress under the edge of the skin, and a restraining bandage over the whole. The next morning the bandage and lint are to be removed, the eye washed and dressed, and the dressings repeated. On the second day, great care must be taken that the ligatures keep the lid sufficiently moist, and if any action has taken place by sufficient at the angles of the incisions, it must be broken through with the lancet. On the third day, the phlebotomy in the forehead should possibly be repeated. The ligatures themselves must be supported by strips of plaster, placed vertically between them, and the edges of the incisions should be treated again with the sulphuric acid of copper, or separated with a probe. In a few days more, the ligatures fall their way out; and by the time the parts are healed, the eyelid will have resumed its natural situation.—*Operative Surgery of the Eye*, p. 21, 5th ed. Operations on the eyes principle are also recommended by Mr. Guthrie for the lower eyelid.

When a surgeon chooses to try the fengshui opera, can he predict to be certain that the children of the

there is no altered in the shape as not to afford much change of efficiency) of the fluid within.

Intermittent, the lower eyelid is much less sensitive than that of the upper eye. The late Mrs. Blandford wrote me this disease often from the same cause which induces it in the upper eyelid, though he is more subject to the possibility of such a case. However, I met with several instances of the affection in consequence of erysipelas nasale, which, as they increased, carried the orbital edge of the tressa *orbis* up, and in the same proportion inflated the ciliary edge towards the edge of the eye.

An invagination of the anterior papillera is sometimes produced by induration and swelling of that part of the conjunctiva which connects the eyelid with the eyeball. In cases of epiblistaria this membrane often lacerates between the latter parts a distinct fold, which is situated just on the inside of the orbital edge of the tarsus, and passes to the outside; while the contraction of the arched ligament draws the ciliary vessels upwards, and induces it between the swelling of the conjunctiva and the eye. In this peculiar case, Mr. Saunders advises us that replacing the eyelid in the early stage of the disease, and maintaining it so until the epiblistaria has been removed by proper means will be found efficient. But when the conjunctiva is much thickened and indurated, Mr. Saunders recommends raising with dressed part of it away, and the application of compresses to keep the orbital margin of the tarsus upwards.—(See also *Travers's Synopsis*, p. 251 and 256.)

Altman has recorded a species of tickling, which originated from the growth and insertion of one of the hairs upon the mucous membrane. The place of exit consisted in plucking out the irritating hair, but it is not mentioned whether it grew again.

TRICHLAMINE Triacaine: (From the French, *three* + *point*, three points, from its point being of a trian-
gular shape.) An anesthetic used for discharging
springs, fluids, and even on then-mortal frost after
revivification of the body, particularly those of the per-
sons, and tissues, vegetables, in cases of necrosis, and
byproducts. Triacaine are also employed for taping the
batteries, electrical systems, etc.

A special constituent of a perfume or cologne, and of a cosmetic, which is so adapted to the firm price of the ingredients, that when the perfume is made, they both enter the mould together with perfect ease, after which the mass being withdrawn, the cosmetic remains in the mould, and gives a ready passage for the first constituent.

which is the most of a dream, and the principles which it is made up of are unconstructed. It would be unwise to say in this book in detail every little particular in the instruction. I shall merely review, when the main principles are given, and seem to detail, the various shades of explanation. So, instead of a list of 110 unimportant shades, some of which were rare, these shades are the larger group for the ready reference of those which are so thick, greenish, or blended with my little and blue subjects.

The incision for positioning the bladder from the rectum should be longer than a crescent incision and of a curved form; i.e., as Mr. Cargoe has explained, it should not be placed too high up the rectum, but the incision be extended.

Sanctus ought always to have at least three tones.

one of full size, another of middling width, and a third of small dimensions. In cases of hydrocele, the latter is often preferable.

TRUSS. (From *trahere*, French.) A bandage or apparatus for keeping a hernia reduced. A truss which falls in position properly should compress the neck of the hernial sac and the ring, or external opening of the hernia, in such a manner, that it prevents the exit of the contents of the abdomen with protrusion with complete security. Hence, it is the indispensable quality of a good truss first, to make of dorsal and equal pressure on the parts involved, with out causing pain or inconvenience to the patient; secondly, not easily to slip out of its right position, in the varying motions and postures of the body.

Trusses are either of an elastic or non-elastic kind. The latter are composed of leather, flannel, dandy, or elastic materials. These cannot be at all depended on, and should therefore be entirely banished from surgery. Hence (as Mr. Lawrence has remarked) the use of the elastic truss varies according to the different states of the disease and to the position of the patient in respiration, a non-elastic bandage being very commonly in its degree of tightness, and keep up till the greatest or little pressure. The question of continuing tightness on when the opening is not entirely closed, and the patient who wears with a bandage may be in a state of constant misery. These also lead an active life, or are obliged to use laborious exertions, will be more particularly exposed to risk. If the patient, after experiencing these effects, endures it merely from the desire of the bandage being tight, he may confine the disease, but he produces other inconveniences. The increased pressure injures the spermatic cord, and may affect the testicle; the inguinal vessels become red, painful, and associated; and the bandage must be entirely laid aside, until the pain has recovered. Richter has often seen, painful translocation of the testicle, hydrocele, and even strangulation, produced from this cause, and entirely destroyed by the employment of a proper truss. (Truss de Hernia, p. 44.) He also saw the pad of a non-elastic bandage excite in the region of the abdominal ring a considerable inflammation, which terminated after a few days in suppuration. The truss is not applied against the rate of the abdomen. The inflammation extended to the neck of the sac and obliterated the part. (De Suppuratione, ed. 3, p. 68, 74.) The spring is a very essential part of every elastic truss, and it consists of a flat long piece of steel, which is adapted to the side of the body on which the hernia is situated. It is not a great many years since the spring used to be made of common iron, and Asseand and Richter express their preference to a mixture of malleable iron and steel, so that the instrument may be moulded by the hand in any particular shape; but, as Mr. Lawrence well observes, a truss which admits of such management must be more or less liable to the objections which apply to elastic bandages, and the only material which possesses the requisite qualities of firmness and elasticity, is well tempered steel. The front part of the steel spring has an expanded form, and when the truss is properly applied, ought to be situated over the mouth of the hernial sac. The spring of a truss has necessarily then a verticality, with the posterior end resting on the spine. Comfort is gained by every it is used to the abdomen together with the rest of the truss on the medial side, a piece of which always easily appears. Trusses of this form with a elastic of weakness, which cannot be given to them by displacing the strap. They keep up the pressure better than even a stronger spring of the common kind. Under the back portion of the anterior end of the spring is placed the pad, which should be adjusted in shape and size to the passage which is intended to be kept up. The steel spring is usually covered with leather, is lined with soft materials, and after being put on the patient, is fastened in its situation by means of a strap, which extends from the rear end of the spring round that side of the body on which the hernia has been situated. Flannel, with the fur outside, is sometimes considered the best covering for preventing the spring from the ill effects of perspiration.

When it is necessary to make strong compressions, as in large old ruptures and in persons who cannot avoid labour and exercise, the elastic spring should be

made accordingly thicker and broader. But in cases of the first-rate importance it is to make the spring gradually upon every point of the body which it covers. This is what demands the greatest attention, but of the responsibility of the instrument maker, especially making use of some individuals are flat and narrow, while those of other persons are broad and protruding. A thick flexible, elastic wire, accurately adjusted round the person, will serve to take the measure and proper shape of the spring, which may afterwards be made a little if forced necessary. The wire, however, should be somewhat longer, on account of the length of the spring.

The springs of trusses intended for children and persons who do not undergo much labour and exercise, need not be made so strong as those designed for the working, active people.

The idea that children cannot wear steel trusses is erroneous as it is dangerous, in its practical consequences; a point on which Mr. Fox has strongly insisted.

Trusses are sometimes fabricated with a pad made of the spring instead of being riveted to it. This may be improved, specially in children, according to the form of the abdomen, and it is inserted at the desired point by a spring fitting into the neck of a stick. In others, the plate consists of a screw, by which the truss is pushed further towards the abdomen in its pressure. Although these cannot be a fault than some of these inventions possess, especially the first, and are in certain instances superiorly useful, a step, we are convinced that in general their utility is not so much greater than that of common pads, as it is made thereby in the word of simplicity and the economy of expense. I should be sorry, however, to say any thing that would unduly discourage of such ingenious attempts to improve an instrument so difficult to bring to perfection at a time; especially as I believe these are particular cases in which pads with curls, screws, springs, &c. may be employed with great advantage.

Notwithstanding every care, sometimes even elastic trusses cannot be tolerated from slipping away from the parts which they are designed to compress. Sometimes they slip downwards, which is in subjects is generally caused by the protrusion of the abdomen. Consequently, the fault consists in the instrument becoming displaced in the direction upwards, where exactly happens in this position, and is produced by the flatness of the abdomen. In the disease, the displacement is to be prevented by the use of an elastic expulser; in the second, the slipping of the pad upwards is to be prevented by the employment of a steel strap.

When a patient is afflicted with a rupture on each side, the two operations may be very well kept up by means of a single truss made with two pads, which are joined together at the external opening of the ring from each other by a piece of steel, applied over the convexity of the apophysis of the pubis, and prolonged in length to the space between the two openings through which the viscera descend. As well as, however, it is absolutely necessary to have the spring stronger than if there were only one rupture. The truss should also be put on that side of the body upon which the hernia most difficult to reduce is situated. Some practitioners, however, use the pressure to the use of two elastic trusses placed together in front and behind with suitable straps.

With respect to the application and use of trusses, the following instructions seem to merit attention.

1. A truss should never be first applied, or changed, except when the patient is in the horizontal position, and it is known with certainty that all the contents of the rupture are completely reduced.

2. The first application of a truss should always be made under the superintendence of the surgeon himself, and care should be taken, in putting on the instrument, to do so in a manner that the lower end of the pad will compress the neck of the hernial sac against the pubis, while the upper portion will compress the abdominal ring. The surgeon should also make the patient acquainted with the right manner of applying the truss; the positions on which it keeps up the bands, and affords a chance of a radical cure; the requisite caution to be observed, &c. When a patient first begins to wear a truss, he should be particularly careful not to be guilty of any inelegant straightening.

less from disease, and in Tawdron are performed in an unobstructed manner. As it is a secret that the same cells of the system (infective) may be within cells and tubercles and elsewhere, may become an individual host. They may be diffused through the tissue of a system, forming swelling in its margin, before, or they may occupy the proportion of it, as seen in the *conspicua* parts, and observe there is the same type of disease (see p. 218). When enlarged growing at tubercles and forming within systems, be considered large size tubercles, the latter conceive that the tubercle apparatus, which at some correspond, in some degree, with the original distribution of the parts. The tubercles (tubercles) are at first large to the right of the parts, to the right of the parts, to the limited extension of the tubercles, and to the amount and consumption of the tubercles. In the latter system they were very many, the largest part being larger than the head of a pin, and their number defied all calculation.

* Other restrictions include arrangements of the elementary part of the model, growth of the total case, corresponding variation in their applications. Thus, when a variable is excluded, it is within the order, and are transmitted into, with variations in a series of three indicators will enable a series of economic factors.

[illegible]

Peasants are said by Arabs to grow from the *cashe* or inner surface of silver coin, or that within there, have seen (says Dr. Harmer), from a variety of this kind, the silver and its appendages converted into an enormous number of small, flat scales of the size of the far growing from it, while these scales were surrounded by smaller ones in many gradations. Some had glaucous margins, others more or less of silveryness, and others were but white changed, having thin delicate, crisp, and sometimes a transverse fold.

[illegible]

has, I must, been showing (says Dr. Buxton) that it is to the loss of the systematic character altogether, and the transformation of this basis, that the natural symptoms in this and many other diseases, are to be referred." (p. 378.)

Although I maintain the evidence and arguments which Dr. Bates has adduced in support of his opinion is unassailable testimony, the facts brought forward do not appear to me to justify the conclusion, that the formation of leucocytes and various granularly depends upon hyaline and their transformation. That hyaline has sometimes been with chemical alterations, and that cells, crystals, granules and fibrillation of various purposes are often evolved in tissues of different kinds, are facts universally received. But the presence of hyaline in the pathological state is only in exceptional circumstances; whereas, if they were generally a cause of leucocytes by undergoing some transformation, it is impossible to suppose, that some of them at least could not be more classically fixed as in distinct, dissolved forms within or around all swellings inclined to proceed from causes of them. As the growth of tumors takes on these principles could not, therefore, be accounted for without supposing a continuous proliferation and transformation of hyaline, either within or around the swelling, one would expect that some visible hyaline would be their transformation, would certainly be apparent on minutely examining the interior and the circumference of the diseased structure. Yet I am not aware that such has been proved to be transpire the mass, either by the aid of the scalpel or the microscope. The observation of crystals, cells, and fibrillated appearances in some kinds of tumors, is no proof that such modifications of structure are transformation hyaline. Besides, if my view would allow me to consider any type further, many reasons might be urged against the hyaline doctrine, arising from the consideration of the changes treated in the blood-vessels supplying parts in which a recognizable tumor is situated. Thus we often see the trunk of the arteries spouting two cells with parts, divided in size, as it were, with respect to the covered on the internal length of the ring's lumen, and ingesting at once that the formation and thence of swellings are effected through the rupture of the blood vessels. The visible effect of being the arteries by which a tumor is supplied with blood, seems also be difficult to explain if the growth of the swelling really depended upon some indirect transformation of hyaline.

It seems to be generally accepted, that the growth of all organisms may be retarded, and that sometimes they may even be destroyed by means of liquid nitrogen with freedom, but keeping the parts in a constantly cool state by the constant application of cold solution of ether. . . . However, when the increased action of the heart is again checked, and the temperature is again lowered, the arteries are relaxed, with as frequent as normal pulsations, growing electrically, reflexively, and so forth, and the heart, lungs, and liver. Very active diseases are arrested, however, are they possibly reversed by these liquid means. The reflex, easily taken, reflexly increases, reflexly, taking them, but the extension of the disease by attention is not directly attended with danger, as the affection becomes changed by them into very serious and dangerous cases, sometimes in all instances (successes). The most effective plan is to maintain the presence of carboxylic vapors with the knife, while they are kept and in an incipient stage, for then they do not die by an operation which is certainly right, compared with pain, might observed become operative, if the disease were allowed to proceed, and still in an incipient state.

Thymus, myrtaceous. These have been raised from their first family fold. They are of many kinds, some of which are single, while others are compound, with a trifoliate leaflet. Mr. Allen has attempted to form a classification of succulent plants, for the different species of which he has proposed names, deduced from the structure which he called on Gussone. The specimens are named after the kind of structure which he first considered. Gussone's names are *Digynous Succulent*. Under this title Alchemilla, including those through which apophysis is increased of the *gynostemium* part of the flower, and also some in which the growth of the leaves is increased.

which are composed of fatty matter only, but the adipose substance is increased, and their structure is looser, only somewhat more compact, so that the fatty substance is more pure of the body.—*Med. Clin. Yvres*, vol. 11, p. 447. This fact is very much against the doctrine which believes the origin of cancers to be in the blood and their transformation. Adipose tumours usually always have a thin covering, derived by the direct development of the surrounding cellular tissue. It adheres very slightly to the vessels, and easily by reflected vessels actually pass through this parietal coat, covering of vessels to the tumour. As Mr. Abernethy has frequently described, the vessels are at first, and the tumour in place, thus increasing the tension to a degree proportionate to the pressure they easily put, the danger between the artery and the capsule, is as to know the little case the vessel, and rarely catch the disease. These individuals seem to have a disposition to the formation of fatty tumours upon various parts of their bodies; as numerous examples of which is recorded in the *Annals*. The patient was a young woman, aged 18, whose constitution was not in any way remarkable. Although very thin, and of the middle stature, she weighed 100 French pounds. Her shoulders were two inches high, slender long and thin. Her arms, of less size, were situated near the right breast. A fourth from the inner angle of the shoulder blade, and half a finger long and an inch. A fifth, lower down, was six inches long and five broad. The sixth, which was larger than a man's head, was situated upon the right leg. The seventh, a small one, was below the right trochanter major. The eighth, a peduncle one, arose from the left hypochondrium, and hung down as low as the middle of the calf of the leg, being two feet long and three feet one inch in circumference at its base. All these tumours were of a fatty nature, soft, even, and quite unaltered with external organs of the vessels.—*Ann. Quarterly Journ. of Foreign Medicine*, vol. 4, p. 515.

The influence of suppose tumours to be very furnished with very large blood-vessels, and the fact of hemorrhage, which frequently does, supports this opinion, is quite uncontroverted. This is an established fact. But there is no species of tumour that can be removed with so much certainty, with such apparent safety, as with such complete security against future consequences as those of the cancer nature. However, now and then, when the tumour has been mistaken in an inflammatory stage, the capsule becomes thickened, and is very difficult to be removed by the surgeon, so that the separation of the tumour is more difficult, and requires the knife to be used freely and deeply. The tumour also sometimes becomes, after inflammation, closely adherent to the surrounding parts. Adipose tumours, often require no treatment whatever. Indeed, there can be no doubt of the fact stated by Mr. Astley Cooper, that they require a greater magnitude than any other swelling ever reaches. Mr. Abernethy has an example of one, removed by Mr. Clark, which weighed between 1000, and 1100, and which was removed previously to the operation.—*Mr. Astley Cooper also mentions the removal of a tumour of several adipose tumours of various size, one weighing 145, that removed by himself, and another weighing 145, removed from a lady's thigh by Mr. Cooper.* For a full and remarkable case is one in which Mr. Astley Cooper has removed a fatty swelling, which weighed independently of the blood in it, 1000 lbs., and was placed on the abdomen of a man aged 57.—*Ann. Med. Clin. Yvres*, vol. 11, p. 440. In one case removed from the *Annals*, removed by M. Dupuy, of Moulins, the weight of the tumour weighed, when it arrived, 45 French pounds.—*Ann. Quarterly Journ. of Foreign Medicine*, vol. 4, p. 515. Although it is true, that when adipose swellings arise in various parts, the tumour is one of the most rapid for their removal and is dangerous, and is a strong argument in favour of having recourse to the operation at an earlier period, yet it is equally true, that large fatty swellings may be taken out with a greater degree of safety than any other kind of tumour of equal size.

The next species of tumour, named in Mr. Abernethy's classification, is what he names sarcoma, from the resemblance of the structure to that of the

granular. This kind of tumour, it is remarked, is occasionally found in the cellular substance; but more frequently in the fibrous tissue, on that part of the body which is next to the skin. When a sarcoma is in the cellular, and fibrous tissue, the surrounding parts and the glands in the axilla are not affected. But some of these swellings derive from their essential character, and become of a very indolent, sometimes even, and sometimes pain, and producing no inflammatory state of the skin covering them, so that it becomes adherent to the surface. The abscesses leading to the surface are also formed, and the glands enlarged. Sarcoma tumours do not grow to a very large size, but when, in progress, is unrestrained, the pain attendant on the disease becomes lancinating, and so severe as to make the patient furnish, and lose their health and strength. Mr. Abernethy remarks, that when the axillary glands become affected, one generally grows to first, and is extremely tender and painful, but afterwards the pain abates, and the part remains indolent. Another is then affected, and goes through the same course.

To another species of sarcoma, Mr. Abernethy applies the epithet named sarcoma, from the resemblance which this tumour contains to the structure of the cellular tissue. This kind of sarcoma, Mr. Abernethy says, he has not often seen. In the example which he has seen, the tumour was about as large as an orange, and situated on a woman's thigh. The swelling was removed by an operation, but the part above and beneath it was a sarcoma, and the patient died of the disease in two months. Mr. Abernethy concludes, that the whole of the tumour had been cut away, but that the remaining parts had a disposition to decay, which was induced by the operation, and that if the nature of the case could have been known beforehand, it would have been quite to have made a fine removal of the substance surrounding the tumour.

Mr. Abernethy places the mixed tumours between such sarcoma swellings as are attended with no malignity, and the following ones which have this quality in a very destructive degree.

The tubercular tumours are composed of a great many small, firm, rounded tumours of different sizes and colors, bounded together by regular substance. Some of the tubercles are as large as a pea, others as a hazelnut in size. Some of them are of a brownish-red color; but some are yellowish. Mr. Abernethy mentions his having seen two species of sarcoma chiefly in the lymphatic glands of the neck. The fibrous tumours are indolent, become a painful and morbid state, and ultimately occasions death.

Another kind of sarcoma, mentioned in Mr. Abernethy's classification of tumours, is distinguished by the epithet sarcoma, from its bearing the appearance of the sarcoma nature of the body. It appears to be a sarcoma, and is a malignant disease, characterized by the lymphatic glands in a similar manner; it is indolent and slow, and at last proves fatal. It is particularly apt to arise in the neck, and is treated of in other parts of this book.—*See Fungus Mammaria, and Tubercle, Diseases of.*

Mr. Abernethy includes also in his classification sarcoma tumours.—*(See Cancer.)*

I have prior to another article (*Mamma, General of*), for the account of the plan of removing sarcoma tumours.

Besides many operations, which have of late years been performed, and are remarkable on account of the great size of the swellings removed, others still more interesting call for attention, on account of the nature and situation of the parts operated on. On the removal of the thyroid gland I need not here dwell, as it is elsewhere noticed (see *Thyroid Gland*); but I feel obliged to mention some other very bad operations, performed within the last few years. The first is that performed by Mr. Goodall, of Bath, in 1800. The case was an immense mass, placed on the left side of the face and neck, and the base of which was about twenty-eight inches in circumference. The disease extended from the external margin of the eye above to within three quarters of an inch of the clavicle below, and some idea of the depth of its extension may be conceived, when it is known that the whole parietal gland was involved in it. For the purpose of

obviating all danger of hæmorrhage, Mr. Goodall began each tying the second artery. The success of the operation will be best understood by adhering to the operation afterwards possessed by the wound. "The whole strumous tract was exposed, and its fibres dissected clean, except about half an inch from its insertion into the clavicle. The wound extended backwards from behind the tracheal vessels to the tracheal arteries, but became narrower in the direction of the trachea at the lower part of the neck. The sub-apophyseal gland was exposed, and almost one-fifth of its substance not appearing healthy was removed. The digastric and the greater portion of the stylohyoid were exposed. The mass of the jaw was only covered by pericardium, which when covered by the masseter muscle, part of which not appearing healthy was dissected away. The whole of the condylar process of that bone was laid bare to the same extent, and behind it the pterygoid muscles were also exposed. The substance of the clavicula was only covered by a cellular substance which did not appear healthy, but sufficient skin was saved to cover the system. The parotid gland was entirely removed." This extensive wound healed in ten weeks, but unfortunately the cure was not permanent; the disease recurred, and eleven months after the operation the poor woman died.—*See Med. Chir. Trans. vol. 7, p. 112, &c. vol. 8, p. 382.*

Regarding the foregoing severe operation, many remarks may be made to doubt the propriety of tying the carotid artery as a preparatory step, and, indeed, it is positively dangerous in all most cases it is attended to the above case; simple temporary pressure on the exposed vessel being represented as preferable. It appears to me, however, that Mr. Goodall acted less justifiably, and on the whole less wisely, because the appearance of the ligature on the carotid had only removed the danger of hæmorrhage during the operation, but created those attended, and he made himself the necessity for a possible, scarlet of ligatures on vessels which would otherwise have joined but a pleasurable quantity of blood.

Now, the necessity is so terrible from the mass branches of the carotid vessels, and more present in the case of a vessel contained in the flow of blood, that the patient may actually die from sudden loss of blood, as nearly happened in another very interesting case of removal of a large tumour involving also the parotid gland, and connected with the treatment process of the artery, the base of the shaft, the trachea, and the pterygoid process, and parts of the jaw. The operator, Mr. Carmichael, in order to complete the dissection, was obliged to divide the trunk of the facial artery: "Instantly (says he) an alarming gush of blood, which evidently came from a large vessel, followed the division, and the danger appeared the more imminent as the pressure, which Mr. T. applied with all the force he could exert upon the carotid trunk, was actually incapable of restraining the current. There was not a moment to be lost. Mr. C. then provided a dry sponge to the bottom of the wound, and firmly pressed on the bleeding vessel, while I made a further incision of the integument till it served as the cavity, occupied by the sponge, with the view of expelling as quickly as possible the mouth of the bleeding vessel. This was accomplished in sufficient time to save the patient's life." Mr. Carmichael, at the conclusion of the history, remarks, that if he were called upon to perform such an operation again, he would, in the first instance, put a ligature under the carotid trunk, which might be tightened or not as occasion should require. The case here spoken of had a successful termination. One shuddering consequence was a paralysis of some of the fibres, brought on by the division of the trunk of the parotid gland in the operation.—*See Trans. of the King's and Queen's College of Physicians, vol. 2, p. 111, &c. Dublin, 1818.*

The last instance which I shall notice of the removal of an aneurysm related to the parotid gland, is that recorded by Ellis, the eminent operating surgeon at St. George's. The patient was a woman of seventy, and the swelling extended from the ear to the shoulder. In the operation, all the branches of the facial artery were divided; a piece of the masseter muscle lying over the external carotid artery and parotid gland was left quite bare; the dissected skin covered by a new skin, and the temporary external aneurysm and carotid

arteries were of course divided along with external arteries of the neck; yet the largest of these being tied, the bleeding was very inconsiderable. The result was so successful, that at the beginning of the next week the wound was entirely healed.

The same distinguished surgeon also removed a large tumour, extending from the larynx to the sternum, and measuring three feet one inch in length, and six feet six inches in circumference. Ellis remarks, that the tumour was the supposition that it was an aneurysm formed by the union of the common carotid, but it proved to be a compound cystic tumour, and extending to the high bone, and in every direction except the anterior, inferior, and lateral parts of the neck. It was, partly, with the finger and partly with the knife, the fatty mass was separated from its membranous contents. Several vessels were cut and secured from the profuse hæmorrhage. However, not more than a quart of blood was lost. The tumour, after its removal, weighed twenty-seven pounds, and three-quarters. The patient, a woman of forty of age, went on very well for eight days, but on the ninth, she was constantly complaining of anæmia in the foot of the affected limb; her pulse became weak and trembling; and six weeks after the operation she expired.—*See Ellis, for History, the Transactions of the King's and Queen's College of Physicians, vol. 2, p. 111, &c. Dublin, 1818, or Quarterly Journal of Foreign Medicine, &c. vol. 12, p. 21.*

In the autumn of 1821, M. Roux removed the whole of the parotid gland, which it seemed to be, but in a truly admirable manner the dissection being, related, and the patient ultimately died of it. The correct dissection was made to be completely to secure the tumour. The portion of it exposed to the atmosphere was first detached. The tumour was then laid to separate the tumour from below upwards, till a portion of it was found resting on a solid point backwards and under the pterygoid process.

As to the removal of the tumour, which it would have been difficult to stop in the operation, M. Roux was determined to cut into the substance of the tumour, at that point where the deep dissection was made, and, then, dissecting from below upwards, he removed the tumour; and, together with it the lower part of the trachea of the patient aneurysm, which participated in the disease. Numerous arteries being now cut, Roux proceeded to the resection of the remainder of the tumour. A part of the trunk and lower portion of the tumour were found divided, and not cut away. Shortly the whole of the dissection below the jaw had been carefully dissected out, when a large jet of arterial blood issued from the external carotid, as one of its branches that it was very well divided. M. Roux placed his left thumb on the point from which the blood issued, and a double ligature was applied, and pressed it to close, the other artery, the internal carotid, in the clasp. The artery was then left behind and a skin patch, which the rest of the gland was dissected out. Only one small continuation of the tumour, situated just below the cervical vertebra, was left, as one of its branches in the typical parotid vein, and it was tied. As the tumour, the aneurysm was now, thereby dissected. The branches of the seventh pair of nerves had been removed in the tumour; the fifth, sixth, seventh, and eighth, however, were preserved in the lower part of the tumour. The general part of the tumour exhibited the mass of parotid gland and strumous condensation aneurysm. Towards the front process, the external carotid and with two ligatures, the stylohyoid, digastric, and, rather more dark, the small part of the trachea that was cut, found in the lower of the tumour which opened into the same aneurysmal formation. The following statement is derived from the case. First, the nature of the nature of the aneurysm was confirmed. Secondly, the ability of removing the tumour completely. Third, the tumour was a source of the aneurysm in the parotid may be stopped by ligature, and the gland it is removed by the first aneurysm that portion of the parotid which is exposed behind the jaw, is dangerous, as opening the carotid might then prove fatal, whereas if the largest portion of the tumour be first removed, and then the rest subsequently and slowly, the danger of aneurysm will be removed, and the tumour which lay over it has been left

away. Fourthly, The symptoms and lesions, by which the patient was affected, attacked on certain days after operations on the face, and the return of discharges discontinued frequently, every where plentifully extinguished. Fifthly, The paralysis of the muscles of the face which took place, is explained by the division of the branches of the seventh pair of nerves. —*See Archives Gèn. de Méd. Agric. 1834.*

Acquiescence may be maintained whether, as some natural arrangements of the parietal gland, and parts extending deeply above the throat, it would not be considered to be in contact with directly rising or falling matter, and trying wastefully stopping this large supply of blood to the diseased parts, would not be followed by an absorption of the matter? Some have ascribed to this opinion a weakening the single discharges, where the tumours by themselves fall under consideration. It was then to be seen, that the result of this experiment is but one of perpetually repeating the growth of a tumour of this kind, and even upon it has this effect at first. This certainly will, no doubt, induce many practitioners to reject the best method of cure. Yet when all things are taken into consideration, notwithstanding its nature is a few instances, it is doubtless severe, and most of itself in the generality of cases and fatal consequences. They will also be encouraged, in very similar instances, to try the effect of the ligature, by the case which Sir A. Cooper accomplished of an enormous cancerous enlargement of the lower extremity, by ligaturing it in the groin. Indeed, I am sure, that as the surgeons in London may arrange, the gift of their patients by cutting off their main supply of blood, will be much more extensively obliged than has hitherto been the case. In this way the cancer may attempt the disposal of many tumours which could not be removed with in any other manner, and which, if left to themselves, must have a fatal termination. With regard to anatomy by dissection, the plan adopted by Mr. White, Mr. Lawrence, and Mr. Brodie, of extending it by a ligature applied round its base, is doubtless preferable to the use of the knife, which may bring on a violent degree of hæmorrhage.

TUMOURS, ENCYSTED. These, which are commonly named *Wens*, consist of a cyst which is differently situated. When the encysted matter is solid, it is termed a *stone*; when more or less fleshy, *melancholy* or like *gum*, *adenoma*. These are the three species into which writers usually divide encysted tumours. However, some of these divisions do not conform to either of the above definitions, as their contents are subject to very great variety, indeed, and are occasionally of an earthy, bony, or bony nature. Some encysted tumours of the latter description are extremely hard, and imitate the appearance of bone, by the gradual projection of the matter secreted within their cysts. —*See Sir Edward Ross's Obs. on the Growth of Bony Tumours, in Phil. Trans. for 1815.* In the year 1824 I attended, with Mr. Lloyd, of Corkinnow, a medical gentleman, from whom I received a variety of new tumors, which had become very troublesome in consequence of its pressure making the parts around it sore and inflamed. It was less cut off early, and by another surgeon, but now again. At present 1828, there is no appearance of its introduction, and when I pointed by carrying the incision very deep, I saw an enormous mass of this kind existed some years ago from the removal of a man in St. Bartholomew's Hospital. Sir James Esq. performed the operation, and, if I am not mistaken, the projection of the tumor before the removal of that hospital. Sir James's most remarkable specimen of such encysted tumors are preserved in the Anatomical Museum of St. Thomas's Hospital; one is 18 inches which resembles a man's horn in shape, and was removed from a gentleman's head at Kingshead, by Mr. Esq. A further account of the case is given in Ross's *Epitaphia*, article *Bony Encysted*.

I possess every bone in Dublin (an exception in the British Museum) the bone exposed to the eye, and which, with another, at the same time, grew upon the head of a cancer subject. What is usually called bony tumors are not, as physicians would imagine, in the vicinity of encysted tumors. (*Epitaphia*, *Phil. Trans. for 1824*, *Vol. 2*, p. 182.) And yet, both more or less frequently formed, have been, and may be, within the

same situation. An interesting specimen of the latter occurrence, in a double encysted tumor in the orbit, was published some time ago by my friend Mr. Barnes, of Exeter. —*See Med. Chir. Trans. vol. 9, p. 316.*

It is observed by Sir Astley Cooper, that it is when encysted tumours are situated upon the temple and upon the eyebrows and other hairy parts, that they sometimes contain hairs. These "have no hairs not curly and differ therefore from those which are produced on members of the body which naturally form hair." In some, the cysts sometimes contain wool — (*See Cooper's Essay*, part 2, p. 225.) The tumours in which these hairy encysted tumors are produced is stated to be as follows: "The hair begins to grow from the open surface of the cyst; as fast it is cut, but soon appears considerable thickness; which it is done, but after a few weeks it assumes the character of hair." (*Idem*, p. 225; see also *Long*, in *Phil. Trans.* for 1811.)

Encysted tumours are generally of a reddish color, and are more elastic than fleshy swellings. However, the latter circumstance depends very much upon the nature of their contents, and the thickness of their cysts. As the very observation extends, extended by means of more frequently on the head than any other part, but only are very frequently met with in the situation under the description, and sometimes in deeper places. Encysted tumours are also very often seen on the eyelids.

According to Sir Astley Cooper, they are in general nearly pedicled, and when viewed on the head first very thin, but upon the face they are encased with a thin membrane and of a pale color. The skin covering them is generally unaltered, but it is soft and then streaked with blood vessels which are larger than those of the surrounding integuments. — In the centre of the tumor on the skin, a white space, that in its early state, a black or dark-colored spot may be seen, which sometimes continues through the whole course of the disease. In general, they are encased with just so much of the integument, and only require removal from the parts in which they exist, and the universally approved way they produce. They issue rarely within the cellular membrane if they are free from inflammation, but the skin in general does not early move over them. — (*See Cooper's Essay*, part 2, p. 230.) The general number of encysted tumours which this experienced surgeon has met with in the same individual, was sixteen, situated upon the head; and he has seen five of another patient, as many as which number occur upon persons themselves. — Four, five, and six, as Sir Astley remarks, are not uncommon. The largest which he has ever seen was equal in size to an ordinary corn, and grew upon the head; but in general they are not more than one or two inches in diameter. He considers them to grow upon hereditarily, as he has often, in a patient himself, "I have several swellings upon my head, and my father (for my mother) had several." They also frequently occur in several of the same family. — (*Idem*, p. 231.)

According to Sir Astley Cooper, when encysted tumours are dissected, some part of their surface is found freely adhering to the skin, while other parts are connected to it merely by the cellular membrane. The cyst itself is usually filled with a soft, fleshy, or bony substance, and in thickness is different parts of the body. On the face it is on the outer surface of the cyst is very thin; but on the back it is much thicker, and on the head it is so thick and so hard that it is often as firm as the thickness of the cornea, and is so elastic that after being compressed, it readily expands again to its former size. Within the cyst, Sir Astley Cooper remarks, there is a lining of cellular which adheres to its interior, and several discharges of the same substance are issued within the fluid. If the vessels of the cyst are injected, they are found to be numerous, but of small size. The cysts are occasionally joint with an ossified state. — (*See Cooper's Essay*, part 2, p. 232, 233.) It is the opinion of Sir Astley Cooper, that encysted tumours arise from the enlargement of the cellular or glandular pores, in consequence of the extension of their contents. — (*Idem*, p. 233.) If this last statement were correct, the fact would furnish another consideration against the view taken of the formation of it, taken by Mr. Ross. There are some tumors, however, which resist the adoption of Sir Astley's explanation; for if encysted tumors were only

effectual method of curing trypsin laparitis of the eye-balls. He admits, however, that the whole portion of the eye-balls of some instances of this nature upon the upper eyelid must be dissected out, because if it be so closely adherent to the corneal, that, if removed, would injure the latter part too much, and produce either an incurable cataract, or an irreparable shortening of the eyeball. But notwithstanding this, near the eyelids may almost always be completely excised, the only exceptions being cases in which the eyelids happen to be attached between the lachrymæ and the eyeballs, and so intimately connected with the iris of these parts, that the work of the eye would not be cut away without permanently destroying the functions of the lachrymal parts of the ocular system. However, when the shortening is not too strongly attached to the margin of the eyelid, then assuming the removal of the whole of the eye. He particularly notices upon the utility of moving the eyeball a good deal about daily, for a few days before the operation, so as to loosen its connection, and consider the subject to point it over the edge of the orbit, where it may be readily found slipping to remove.—(*M. 2, p. 512*.) Removing a few instances in which the eye has detached, and firmly adhered to the eye. But has never found it necessary, in the removal of corneal shagbills of the eye-balls, to remove any part of the lachrymæ; and he has not seen any case of this kind in which were as large as a goose's or hen's egg. The incision through the skin, however, should be deeper than the lachrymæ, so as to facilitate the separation of the detached eye.—(*M. 2, p. 512*.) When it is not advisable, for reasons above stated, to attempt to dissect out every particle of the eye, then fill the cavity with lint, till the wound suppurates, and if this plan is not sufficient, to apply trepan and cauterise. It is related by the Author Cooper, that ocular tumours at the lachrymal orifices are often cured by the use of trepan, on account of their coming into the eye, and being adherent to the membrane.—(*Surgical Essays, part 2, p. 511*.) Professor Wilson has recently recommended making the incision for the extraction of ocular swellings of the eyelids on the inside of these parts. But as Mr. Trauer correctly remarks, the eyelids are often swollen considerably, and being connected with the eyeball; in which case, the operation should be done on the outside of the eyeball. The latter writer admits, however, that the eye is often joined to even the membrane and the lachrymal membrane which covers it; and, in his opinion, it is only when an oblique adhesion exists, and the performance of a white circumscissed, infundibular is precluded, the external lachrymæ, that the incision should be performed on the inside of the eyeball by dividing the conjunctiva.—(*Spurious of the Diseases of the Eye, p. 107*.)

[illegible][illegible]

thence he proceeds by degrees towards the moon in random aim. In favour of this method, he offers the following considerations:—1. By this, an artery is kept a lifetime should be cut, it thus soon becomes fully created, as the case of the tail-artery is already partly decided. The lowered swelling may also be drawn away by the large vessels with the hæmorrhoidals. Langenbeck never introduces the knife simply while there are large blood-vessels there, but pulls the swelling upwards, and then divides the artery in substance with a scissor, which is situated upon the already exposed portion of the fibrous. In this manner the swelling can always be drawn near, and drawn away from the vessels, until at last there is no danger of wounding them. By attending to these principles, Langenbeck has succeeded in removing many very large tumours from the neck, where nearly all the muscles of that part were exposed by the dissection, with the greatest success. 2. After one of these operations, not only the syphilitic process could be fully let off the muscles remaining soon at work by the healthy ones.—(Linn. *de Syphil.* 5. 2. p. 312, 3. 3. *Mon. Gallien.* 1885.) 3. G. Deleens has published, in the second volume of his *Chirurgie Oculaire*, numerous cases of what the French call *opht.* (opht.), including, besides the ordinary encysted tumour of conjunctival vessels, lymphoma, deposit of the stroma, and certain collections of fluid, fluid was again to be drawn by us with chronic or serofolious syringes. The first case, which consisted of a very large collection of imperious nature and more fluid, in the neck of a female, was one of this latter description, though, on section of the tumor being composed of a pouch, the disease might equally be called a cyst, or an encysted swelling. The treatment of this first form of type, the sero-mucous, as he names them, consists in opening them, discharging their contents, and then promoting inflammation and absorption of their white effluent by drying them with chloride, and pointing in this method with three caustics one after the other. An enormous encysted tumour, which had been increasing in size for twenty years past, attended with displacement of the eye, likewise enlargement of the orbit, and other deformity, was successfully treated in the same manner. And, lastly, a patient, a small boy, containing three masses of yellowish limpid fluid, and causing a protrusion of the eye, was cured in a similar way. According to Deleens, the treatment of encysted swellings should depend upon the disposition of their cysts. Some cysts are thin and transparent, others contain latex, mixed with

1898] *in remota causa*, this part should be accepted. 16. A parasite may be eradicated with little trouble, when one has been previously made with out all success, provided care be taken to make the opening precisely in the situation of the former. 17. In these last cases, if the patient's strength be not much reduced, Delpech continues the attempt, established an artificial duct by leaving in the parietes an elastic *fine catheter*, lest if inflammation come on, the solution is to be repeated. 18. *Le Drain*'s operation of passing a fine bisturi into the cyst (*le Parc* certainly) is considered, as likely to cause peritonitis, and aggravate what Delpech calls *un écou* without foundation; the commoner method aimed at the cyst. These consequences he thinks the most likely to follow, were either parties, that each treatment produces an artificial modification of the cyst. 19. An inflammation of the large cavity of the sac, he considers, is sometimes the cause of death, even without peritonitis. 20. Every thing that is known respecting internal eyes, serves in Delpech, that they are incapable of supporting the kind of treatment which takes place in the external ones; and when procured and kept open, whether they inflate or not, they inflame, and are thrown into abscess, but still retain their cavity, and the property of secreting the same fluid as heretofore; that when the parietes close, the fluid film and expands again, sometimes with its natural degree of vascularity; that the membrane that lines the internal eye spontaneously; that the inflammation, caused by leaving the eye with a history is not more efficient in opening up tubular communications, than when followed either a simple puncture, or if the glass is covered by film of keeping up a Guérin's aperture; that the practice of an incision and, in somewhat points, have most frequently only terminated in the formation of such an opening; that, in a few rare examples, in which the operation produced a complete obliteration of the cavity, the tubular eye was destroyed, by gangrene. 21. The project of treating an oval cyst (like a hydrocele) is strongly disapproved of by Delpech, with wholely explains the observations of some surgeons of this kind leads us fairly to conclude.—(*See Pigeur's* *op.*)

It appears to me, that notwithstanding the possibility of the accident, Tolpuck overrates the danger of inferred hemorrhages from passing an oval cyst; and that he ought to have admitted the serous indentation, the depression of breathing, the extension of urine, and other urgent symptoms, often produced by the great pressure of the swelling, as circumstances rendering the operation indispensable for the present relief of the patient. The reader may usefully consult what has been here said with that part of the article *Furunculosis* which treats of scirrhal dropsy.—*Prof. 1*

The *Frontal* of some of the most important theories popular in Germany, from 1820. By Robert Guzik, M.D. In the fourth number of this valuable and practical work, the reader will find nearly identical attempts to polytypic of the nervous. The present, he observes, is continuously mistaken for a long time in the nervous system, the patient, instead of a continuous, typically and moderately, has frequent and great, two meanings from the system, and in the, success, a pair of discharges. These gradually drive the circulation and induce the health, and she requires the daily patients, and induce the complaints, which are the ordinary effects of difficulty of blood. The absence of pain from the signs of polytypic, the three in other cases, and the fact that depth which stands the nature of the disease of this organ, prevents all suspicion that the hemorrhage depends a disease of structure. Types that changes are given in various forms; one primitive is considered after another, and at length, the system is examined, and a polytypic is discovered. In maintaining the nature of the system, for the purpose of determining the property of removing it by an operation. Dr. Guzik explains the mode of treatment as one of the chief points, and in this respect, what is true of polytypic of the frontal is true of polytypic of the neck and others. In polytypic of the frontal, the skull is completely removed by the neck of the nerves, and if the finger can be introduced into the skull, it makes easily passed between the skull and the remaining neck. In polytypic of the neck, the

finger cannot be passed quite round the neck. It may be pinched partly round it; but it is stopped when it comes to that point at which it is attracted to the neck. In polygons of the edge of the vesicle, the stalk does not enter the orifice, but grows from the edge of it, and is not separable by it. With respect to the structure of polyoid Dr. Gould describes them, when cut again, as presenting a hard whitish substance intersected by numerous partitions; but he adds that they are sometimes of a much softer and looser consistency, and sometimes have tooth-like cavities in them. Their external covering is the granose substance of the uterus. Their internal vessels are differential cases. Dr. Gould has observed several which were as large as the head of a new-born child. They are commonly of a tough, more elastic sort, and he has known several cases in which frequent hemorrhages were contained by a polyoid not larger than a wheat, attached just within the os of the neck of the uterus.

According to Dr. Goetz, a polypus of this kind has often sometimes passes through the entire of the neck polypoid and immovably; sometimes suddenly, during the action of the bowels. He has known several instances, in which patients, after this action, were suddenly seized with extension of arms, and, on examination, a polypus was found in the vagina, compressing the cervix.

Another valuable observation, made by Dr. Goody, is that the bleeding comes from the tumor and not from the claret itself; for "as soon as a ligature is applied, and released, regard the milk, the hemorrhage from that time ceases, although it only be several days before the tumor comes away." He notices the opinion of M. Leroy, that a polypus does not bleed while it remains within the uterus; but that after its expulsion into the vagina, the efflux of the uterus, by compressing it still, expels the return of blood to the vein, which immediately hard and dried profusely. The incompleteness of the first part of this experiment he cautiously reserves.

Two salivary glands are likely to be indications for prolyl, are, first, the parotid gland; and, second, the sublingual gland. Salivary glandular excretions from the former, is a prototype, besides the indications usually noticed, Dr. Good advertises to the sensibility of the former men (Gleason) a polysar being insensible, so that if prolyl or scratched the patient does not feel it. With regard to leishmaniasis, when this is only partial, that is when only the border depends through the on the on into the surface, and the patient is recovered for many months, the disease feels exactly like a polysar of the border. Here the skin is itching and the disease is its usual state, and the time of its first appearance, which must have been immediately after delivery.

When there is doubt, whether the case is a polypus or a malignant excrescence, De Goech recommends the application of a ligature. If the swelling has a stick which can be tied without any danger of including the neck in the folds of the tumor. According to his experience, the plan succeeds in an immense proportion of cases, and he has known it succeed in several attended with a cannibal's eagerness of the patient. Even if the excrescence should return, the patient, he says, would not be sorry if this was the case.

This excellent physician not only enjoys the constant observance of the practical rule recommended by all men of good judgment and experience; namely, that whenever hemorrhages from the uterus resist the ordinary means, the nature of the case should be verified by internal examination.

For the eradication of polyps, Dr. Green prescribes two baths, including those described and repeated in Richter's Elements of Surgery, and my First Course of the Practice of Surgery; but they are straight instead of being curved, which last advice he holds very important. The danger of including the uterus in the ligature, he thinks, may always be avoided by the following rules. 1. Extended always at joining the ligature as high as possible on the stalk, it is to be passed as low as possible, care being taken, however, to pass it over the body of the tumour. He reasons by experience, that the portion of stalk left above the ligature will not grow again, but, like the remnant of umbilical cord and falls away. 2. When the stalk grows below the cervix, or the os uteri, if it can be felt, seal best above the neck and the neck below. The

texture might, as we applied a little below the cribriform. If this channel be left, the part best guide is the ordinary length of the projecting part of the neck, that is, about one-third of an inch. When the polypus is very large, and the vagina closely contracted, it is difficult, or impossible, to touch the stalk and the cervix, so as to make an accurate measurement, but the first rule only is practicable. 3. To attend to the condition of the patient when the ligature is tightened; for if it give much pain, a part of the ligature is soon probably included.

When a polypus grows from the neck or lip of the uterus, it sometimes becomes merely an obstacle and proves innocuous. A case is related by Dr. Good, exemplifying this fact, and the great facility of dissection of the uterus to be mistaken, unless a careful dissection be instituted.

Women who have a polypus, especially one growing from the neck or lip of the uterus, sometimes become

pregnant. Of this Dr. Good has known two instances. In one, the tumour was discovered in the fifth month of pregnancy, and was removed by ligature. The pregnancy went on to the sixth month, when the patient was safely delivered. In the other case it was not discovered till the commencement of labour, and it produced death a few hours after delivery.

After relating, briefly, respected cases, and adding some valuable reflections on the numerous ability to be acquired for surgery, Dr. Good concludes with an account, well deserving of consideration, namely, that "whereas for the cure of cancerous diseases, we are on or even forty of our best physicians, and fifty of our surgeons or midwives, who are of the same rank, every medical man should study Dr. Good's work most attentively, for it abounds in every practical instruction."—Prof.

TYMPANUM. For an account of its disease, see Ear.

U

ULCERATION is the process by which sores or ulcers are produced in various bodies. In this operation, the lymphatic vessels are at first to be seen in the blood-vessels. Anyhow is a class, formed on the surface of the body by the removal of parts back into the system by the action of the absorbents. At first, it may be difficult to conceive how a part of the body can be removed by itself, but there is no more difficulty in conceiving this, than how the body can form itself. Both facts are equally well explained. When it becomes necessary that some whole living parts should be removed, it is evident, says Mr. Hunter, that nature, in order to effect this object, must not only confer a new activity on the absorbents, but must throw the part to be absorbed into a state which yields to this operation. The absorption of whole parts is derived from five causes: pressure; irritation of irritating substances; weakness; distention of parts; death of them.—*Hunter on the Venous System*, &c. p. 442—443.

Ulceration takes place much more readily in the cellular and adipose substance, than in muscles, tendons, ligaments, nerves, and blood-vessels. Hence, in the progress of putrification of the body, ulceration often takes a superficial course for the purpose of bringing the matter to the skin. The skin itself, also, being highly organized, considerably retards the healing of ulcers. On the same account, when absorption is suspended, the edges of the skin hang over the ulcerated surface.—*Hunter*, p. 447—448. There is a considerable distance from the source of the circulation are generally more disposed to ulcerate, than others situated nearer to the heart; hence, one source of the greater number of ulcers on the lower extremities, than on the arms.

Non-fused parts, such as cicatrices, callus, and all analogous new matter, like ulcers, readily admit of being absorbed. Thus, in Lord Atter's voyage, when the crew of the ship began to suffer from great privations, fatigue, the scurvy, &c., it was remarked, that such men as had had ulcers and broken bones cured, became again disabled by their ulcers breaking out afresh, and the cause of their obliquities being renewed. The absorbent system is even more prone to be disturbed than what is said to be a substitute for the old. Mr. Hunter explained this circumstance on the principle of weakness.

When ulceration takes place in consequence of the death of an important part, it causes then an ulcerated state, between the dead and living substance. A cancer, when it breaks light, presents in every direction a new, with one mode of way is an ulcerated state, because when Mr. Hunter found that ulceration happens in an ulcerated state.—(P. 442.)

The particular difference in ulcers, or any analogous substance, and the natural surface, are those which are most susceptible of absorption. This is one of the most curious phenomena observed in the process under consideration. Inasmuch that there is a principle in the human body by which parts are always prone to free themselves from disease. Signs pressure

from without will often produce a discharge of pus, and hence, Mr. Hunter remarks, they may appear to be a corresponding backwardness to other forms.—(P. 443.) Both these facts, he observes, are shown in the case of Rupture (achyria); for, though the water is absorbed the cavity of the test, and a tumor in any extremity, by means of absorbing, with the Schenckian medicine even before mentioned, was to become a tumor against the progress of the fluid towards.—(P. 441.)

Not infrequently, as Mr. A. Cooper has remarked, matter forms behind the scrotum, due to the pus and perforation, which constitutes an ordinary sign. From the quantity of these abscesses, it might be expected, that the matter would pressure upon the testis, and by distending it, the cavity of the testis, distending it. Instead of this, however, the pleura undergoes no other alteration than that of becoming thickened; and while it is passing the addition of substance, the process of absorption is going on in the inner part of the system, so system is forced through it, and the matter is voided externally. The same fact is exemplified in abscess within the peritoneum and abdominal cavity. Abscess of the liver, however, generally how low the stomach or bowels, which are more in front than the skin, and afford also a passage for the matter.—(P. 442.)—*Cooper*, vol. 1, p. 322.

There is one difference between the absorption of an elevated tumour to the surface of the body, and the progress of an abscess in the inner system, viz. that the former depends entirely on the action of the lymphatic absorption of the blood parts, between the skin and skin; the latter and external the same process, in which period inflammation takes place, and absorption becomes accelerated less elevation. In an abscess, the progressive absorption begins in the first of the parts that the internal absorption is the second part covering the matter is going on.—(P. 442—443.)

The action of progressive absorption is to prevent surface, consequently to irritate causes which Mr. Hunter referred to pressure, irritation, and weakness. In cases of pressure, pressure becomes a sign. The tumours and signs of pressure are the first of the two kinds of absorption. The facts of pressure and inflammation, which have agreed with the same process, all apt to absorb. In the lower extremities, Mr. Hunter observed, that absorption is a substitute for absorption, and is, at the same time, a proof of a certain degree of strength; viz. if the patient's constitution were not weak, the same parts would absorb.—(P. 442.) The pressure is a frequent cause of absorption, it is not effected by the increased action of the lymphatic system, but by the action of the blood.

That irritating substances produce absorption, needs no illustration.

Progressive absorption may take either with or without suppuration. We have instances of neither in cases of extraneous bodies, which are evident

the body, without producing irritation enough to give rise to the secretion of pus. In the progress of emphysema of the lungs, and in fungus tracheæ of the larynx, the matter in the surface, the same fact is also illustrated.—(P. 425.)

Altered in its appearance, in other words, discolored, either happens in consequence of suppuration already begun, in which event the pus acts as pressure, or from absorption of the cutaneous surface (from particular irritation, or breakdown, in which case suppuration has not taken place).—(P. 426.)

The production of absorption requires much greater pressure than without that from within. The process is always supposed to take place more quickly when near the surface of the body, and its progress becomes accelerated in proportion as it is near the skin.

The adhesive inflammation proceeds the suppuration, and prevents the pus from becoming diffused so soon as it is wanted; and when the first adhesion is made, in order for the latter to approach the skin, the adhesive inflammation will continue to go before the suppuration process, and thus prevent the matter from penetrating their into the cavities of the cellular substance.—(P. 427.)

The pain of ulcers is, in some degree, peculiar to them in its character. When suppuration begins on a surface, it takes place, for the purpose of bringing matter to the skin, the pain is always considerable. When suppuration takes place, in order to separate a dead part, as in abscesses, carbuncles, &c., there is seldom any particular pain.—(P. 428.)

The bleeding seen always exhibits little variety, while the skin is unbroken, and this, at the same time, forming a little out, and sometimes, even in the ulcerated surface. The face of the ulcer appears flat, and the discharge heavy this.

When suppuration stops, the edges of the skin become regular, smooth, a little rounded, or turned in, and of a purple color, covered with some transparent white.—(Illustr. in *Legislation*, &c. p. 390.)

The reader, desirous of further information, should particularly consult the last publication, and *Thomson's Legislation*, p. 390, &c.

ULCERS. *Thomson* generally defines an ulcer to be a solution of continuity in any of the soft parts of the body, attended with a secretion of pus, or some kind of discharge. "A granulating surface, covering matter," has been proposed as a definition. J. A. Cooper, *Lectures*, &c. p. 192; which is very applicable when ulcers have formed granulations, but cannot include cases, in which the effects of absorption are extending, and the granulating process has not yet commenced.

In the present part of this Dictionary, there will not be occasion to speak of several kinds of ulcers, which have been treated of in other articles.—See *Cancer*, *Cancer Cris*, *Chancres*, *Fistula*, *Malignant Gangrene*, *Lupus*, *Ulcers*, *Scrophulous*, *Sicca*, and *Furuncular Ulcers*.

Ulcers are divided into local and constitutional. As Professor Thomson has well observed, however, it is only within certain limits that this distinction is well founded: for an ulcer, which is at first completely local, may in time affect the system so as to become constitutional; and ulcers, which derive their origin from some general affection of the system, may result after the removal of the constitutional disorder by which they were originally produced.—(*Lectures on Legislation*, p. 427.)

Ulcers vary, Dr. Thomson, has well observed, however, it is only within certain limits that this distinction is well founded: for an ulcer, which is at first completely local, may in time affect the system so as to become constitutional; and ulcers, which derive their origin from some general affection of the system, may result after the removal of the constitutional disorder by which they were originally produced.—(*Lectures on Legislation*, p. 427.)

Ulcers vary, Dr. Thomson, has well observed, however, it is only within certain limits that this distinction is well founded: for an ulcer, which is at first completely local, may in time affect the system so as to become constitutional; and ulcers, which derive their origin from some general affection of the system, may result after the removal of the constitutional disorder by which they were originally produced.—(*Lectures on Legislation*, p. 427.)

have examples in the scrophulous, scorbutic, and syphilitic diseases, and also in the syphilitic disease, or chancre which arises not infrequently in those who have had syphilis, from the too free and injudicious use of mercury.

"Every ulcer, strictly speaking, is of a local nature; but there are ulcers which, though essentially local in their appearance, are connected with, or dependent upon, diseases which affect the general system. These ulcers ought to be regarded as modifications of, or lesions in which the disease appears, with which they are connected. Considered in this light, it is obvious that specific ulcers can be treated of with propriety only under the head of the disease to which they respectively belong.

"We call these ulcers ulcers which do not appear to proceed from any specific disease or partial disease existing in the constitution of those in whom they take place. They are usually *ulcers* *scrophulous*, and the consequences of accidental injuries and improper modes of management. They may occur in every part of the body, but they appear most frequently upon the lower extremities."

Professor Thomson, afterwards remarks, that "the appearance which different ulcers exhibit, even at first view, is so different from each other, that distinctions among them, and so they moderately in many respects."

"But (says he) it is to be regretted, that the characteristics upon which the distinctions of ulcers, as well as of many other local diseases, are founded, are neither very uniform in their appearance, nor very easily distinguishable from one another. Not only are the local appearances which present themselves in ulcers liable to great variations in the different stages of the local and general affections, but they are often apparently the same with, or at least very nearly indistinguishable from, those which occur in specific diseases, and which require for their due peculiar modes of treatment. It is this circumstance which renders it so necessary for us, in endeavoring to distinguish and to cure ulcers, to avoid ourselves of all the information which can be procured from the history of the ulcer, from the nature of the exciting cause by which it has been induced, and from the effects of the remedies which have been employed, as well as from the particular appearances which the ulcer itself exhibits."

In noticing another ground of distinction among ulcers, as that derived from the part in which they occur, Dr. Thomson observes, that "every lesion and sign of the body presents physical and vital qualities peculiar to itself; and these qualities must necessarily modify the appearances which each lesion and sign respectively exhibits in the state of disease. Specific diseases under some parts more stable than others in modes of operation. This secondary syphilis appears most frequently in the throat; scrophulous in the groin; cancer in the lower lip; and lupus and scrophulous ulcers in the upper lip or in the nose. Cancer seldom or never appears primarily in the upper lip; but syphilis, when it attacks this part, puts on many of the appearances of cancer?" a fact which Dr. Thomson says, he has learned from Mr. Pott.—(*On Legislation*, p. 425—426.)

In the valuable treatise on ulcers published by Sir Erasmus Home, those ulcers are divided into six principal kinds, viz:

1. Ulcers in parts which have sufficient strength to carry on the action necessary for their recovery.
2. Ulcers in parts which are too weak for that purpose.
3. Ulcers in parts whose action is too violent to form healthy granulations, whether this arise from the state of the parts or of the constitution.
4. Ulcers in parts whose action is too indolent, whether this arise from the state of the parts or of the constitution.
5. Ulcers in parts which have acquired some specific action, either from a diseased state of the parts or of the constitution.
6. Ulcers in parts which are prevented from healing by a various state of the superficial vasa of the upper part of the limb.

Although I have chosen, in the subsequent chapters, to adopt this nomenclature, I am perfectly aware of its being in some respects objectionable; but especially because it assumes hypothesis, the truth of which can

never be established for good. This is one of the considerations which have induced Professor Thomson to prefer the old ointment.—(*Cyclop.* p. 65—132.)

OF ULCERS IN PARTS WHICH HAVE SUFFICIENT STRENGTH TO CARRY ON THE ACTION NECESSARY FOR THEIR RECOVERY: SIMPLE, PUNCTATE, OR HEALING PLEGMA.

In this species of ulcer, the part is of a white colour, thick, smooth, and readily separates from the surface of the sore, and when dried and examined in a microscope, is found to be made up of small granules, resting on a transparent fluid. The granulations are small, hard, and piled up to the top. As soon as they have risen to the level of the surrounding skin, there is a rise in the old skin, which becomes smooth, and covered with a thin, transparent film, which gives it a white, becoming opaque and later white.

In the treatment, it is really necessary to keep the surface clean, and prevent the natural processes from being interrupted. Sir E. Home observes, and this is in general best done by the application of dry lint, for the purpose of absorbing and retaining the matter, which serves as a sort of coating for the granulations, and by putting over the lint a pledget of any simple ointment, in order to hinder the matter from separating, by which means the dressings will not become adherent, and may be easily taken off as often as requisite.

Although healthy ulcers require no medicinal application to be made to them, the dressings must be such as do not disagree with the granulations or surrounding skin.

In some patients, a roller, applied with moderate pressure, with a view of retaining the dressings, will cause irritation, and make the sore less in tendency to heal. Sir E. Home has seen several cases of this kind, in which the proper granulation of the sore returned as soon as the bandage was discontinued.

In some patients, distant trifles and influences of the neighbouring skin; and certain superficial sores will not heal while kept in a moist state, and disordered by the air; but when allowed to become dry and covered with a scab.

These peculiarities are referred by the preceding author to constitutional causes, and not diseases; for the ulcer is local as soon as the particular things which disordered granulation is discontinued. These peculiarities in certain healthy sores may also attend others of a different description, and should always be distinguished from the effects of disease.

1. Application to the form of vessels, and formation, should never be neglected, as they render the bottom of the granulations loose, and disperse the discharges to large skin.

2. With respect to local applications, Sir E. Home also very properly condemns poisons as well as irritations. The use of alcohol as being an application which prevents the formation of a scab, when this mode of cure is chosen.

3. As regards to contrary, there is only one, in that of healthy ulcers, is to keep the matter from separating. The most suitable ointment is the best for the purpose; particularly one composed of olive-oil and white wax.

Sir E. Home observes, that the great objection to the various ointments is, that they sometimes disagree with the skin, even when used and free from all sensibility. When they have acquired the latter quality, they will more frequently create a greater degree of irritation.

4. With respect to applications in the form of powder, Sir E. Home remarks, that when it is desirable to form a scab on the ulcer, any sort of powder may be resorted to; but he prefers dry lint. Nothing should touch the powder or lint; and in several instances, Sir E. Home recommends applying a little balsam on each side of the sore, and over them a roller, which will as firm one below to the other as the means of a lotion.

For healthy ulcers, dry lint is to be regarded as being upon the whole the most simple application. When the use does not require for strength in itself, but to prevent the skin from the discharges are to be changed only every other day.

When a moderately firm bandage is not retained by constitutional peculiarities, it is useful both in sup-

porting the scab and with which are often in a daily state from the greater softness of the skin, and in draining the deeply-strained parts.

ULCERS IN PARTS WHICH ARE TOO WEAK TO CARRY ON THE ACTION NECESSARY FOR THEIR RECOVERY.

There is no second of the classes into which Sir E. Home has divided ulcers in this class.

The granulations of these sores are large, and rolled on their external surface, and of a less compact texture, than those formed on skin in healthy parts. Sir E. Home has also noticed their disposition to separate. When they have fed up the surface of an ulcer to a level with the surface of the skin, they do not readily leave skin, but rising up in a sort of mass, often loose together, the power of producing new cells. When the parts are still weak, the granulations sometimes continue gradually to rise up the hollow of the ulcer, and then, at a sudden, are suddenly absorbed, so as to leave the sore in deeper and lower.

Ulcers may be weak from the first, or become so in the progress of the case. Even granulations of the most healthy kind, if they are not dried over in a certain time, gradually lose their vitality.

Sores on the legs are greatly under the influence of all moral peculiarities of the constitution, and every thing which affects the health. When the system thus becomes in the least debilitated or changed, the appearance of the granulations becomes changed, and they, and the effect of constitutional weakness, or strength, on ulcers, is greater in proportion to the time as farther from the source of the circulation.

While the constitution is undergoing any kind of disturbance, the healing of an ulcer is impeded. Moral economy is very apt to retard cure.

Each effects of the constitutional kind in ulcers are greater in weak and delicate persons than in the strong and robust. Changes of weather have considerable influence on the healing of sores. Sir E. Home observes, in proof of this fact, that when there were several hospitals of ulcers in the Naval Hospital at St. George's, in 1776, proof that the weather changed from dry to a moderate, the ulcers generally seemed as if they were healing; but just as each began to heal when the weather became dry again.

In the treatment of this kind of ulcer, there is no doubt, but that the mind and soul, and not the body, which changes with the constitution, is to be attended. Wise and civilised methods are also necessary prescribed. For, however, it should find that one is working people.

Sir E. Home observes, that the best object in the local part of the treatment, is to keep the granulations from rising above the edge of the surrounding skin. This granulation (in my opinion) very judiciously prevents the greater propensity of preventing the granulations from ever becoming too high by the establishment of proper applications, thus following the common path of destroying the high granulations with a chariot, after they have risen to an improper height. There cannot be the smallest doubt, that if the granulations could always be prevented from rising too soon, the patient would suffer a great deal less pain.

Instead of applying to the surface of the ulcers any under consideration here matter, but varied, and not perceptible, Sir E. Home prefers raising these with rollers with other substances, so as to keep them only strong, and not, and using them in the latter sense. He conceives that when the high granulations are destroyed with equanimity, the disposition of the surface underneath to regenerate them is increased, but that this is not the case when the granulations are only destroyed so as to become absorbed. He observes that when natural processes proceed with great rapidity they are, like vegetable ones, weaker than when produced less speedily. Hence he is of opinion, that the growth of granulations ought to be checked in the early stage of their formation, by some means which they are just able to overcome, and which circumstances they derive strength from the action instead of action which they are adapted to undergo.

On the same principle, according to Sir E. Home, the pressure of tight bandages is unnecessary, and ulcers which heal while the patient is walking about,

are not so apt to break out again as others healed while the pills are in a state of perspiration.

In the treatment of lung abscess, when the pus has been allowed to come to a proper length, and does not form a thin, watery transparent puslike effluvia, three methods may be resorted to, (a) as small parts and limited abscess only. In this circumstance, when the participation of contiguous lobes, lobules, or E. Hesse's circumstances have been made with it this piece of lung over the abscess, and separated with a fine knife.

Among the ingredients to the healing process, Dr. A. Cooper mentions the jagged edges of a wire, smeared by the glassy, sand-like material appearance of the granulations already described. The drainage, examined by him for the improvement of an ulcer in this toothless ear, the long, hydrocarbon-oxygen, which, however, is said to produce a thickening of the outside at the edge of the wire, preventing the growth of the granulations at that part, and replacing the application of the wax, by a diet. On its correction, a bottle of the weight of zinc, two grains to one ounce of water; a solution of the sulphate of copper, one grain to one ounce of water; and a solution of one grain of oxy-sulphate of mercury in an ounce of rose-water. A rubber is to be applied, the diet is to be nutritious, and the patient to take exercise.—(Lancet, vol. 1, p. 187.)

OF APPLICATIONS TO EASES ATTENDED WITH HEAR-
ING.

Although strictly, we have no topical applications which can directly stimulate strength in granulations, there are certainly some which prevent the granulations from exhausting themselves by ingesting growth, and stimulate them to draw more blood from the arteries, which effects, as Sir K. Brown remarks, regular and granulation effluence.

1. This principle is very properly confined to applications to work-stories, as relating formations exclusively employed and so on; and, instead of them, the use of spirit of wire and the direction of poles in such propositions, not, however, to be applied to it.

2. With regard to water absorption, the ratio between exposure and desorption of particles, and within a week of the end of the exposure, is approximately 1:1, as the most stable condition is an anhydrous form.

[illegible]

Mr E. H. Rieuwerts has recently explained, of plaster of Paris or Portland cement, employed with the view of promoting the formation of skin. Perforated plaster can be spoken of as being more adapted to breathe than solid stone. The pores produced should, as previously applicable to the latter kind of skin; however it represents the human growth of the epidermis, besides their skin and respect, and dispose them to form skin. When, however, the growths come upon their skin the level of the skin, it is not posterior enough to prevent decay. When the skin is too much so, it is to be noted within a few days of death.

Agnes of 181, a little less than five years, is always in the parson's study, and named with pride of simple manners.

2. Osteomyelitis resulting in the H. Hoar, are particularly apt to involve the weak system. When the inflammation is not, however, grave cases may be tried, and the same treatment gives a preference to the use of hydrazine salts, joined with iron's salt, in the proportion of one by five, or when in common salts, blended with a small quantity of the hydrazine, nitrate salts.

BY VIOLATING THESE FUNDAMENTAL PRINCIPLES ARE TOO EASY TO FIND ANOTHER TRANSITION, EITHER FROM THE PAST TO THE FUTURE, OR THE COMPLETION OF A PARTIAL, MANIFESTED, OR ACHIEVING STATE.

There are three points to the investigation regarding the nature of abuse, as mentioned by the authors of the present study: are there any differences in the nature of abuse between the different types of abuse? are there any differences in the nature of abuse between the different types of abuse? are there any differences in the nature of abuse between the different types of abuse?

unusually large: and, lastly, a diseased state, by which they are affected.

An intimate and an intimate story cannot, in general, be distinguished from each other by mere appearance, whether they may be so in a few instances. Mr. S. Howe thinks so, that the depicting of an story, like the depiction of a constitution, can only be accurately achieved by determining the scenes which arise from the different interactions made known.

The following appearance, he says, is only above the skin to be of an irritable kind. The margins of the participating skin being jagged and resembling in no wise a fishy leathery and undermined. The bottom of the skin being made up of convolutions of different kind. There being no distinct appearance of grains, inters, but a whitish spongy substance covered in a thin intense discharge. Every thing thus produced the surface gives place, and very commonly scales ill-fitted. The discharge is derived from corners, pus & this field, is proportion to the degree of irritability communicated to the sore by constitutional causes. In general, the pain of an irritable sore gradually becomes less. When it is not constant, but occurs in fits, pains come chiefly in the evening, or night-time, with great violence, considerable numbers of the humors are due to occur, and extend in various other parts. So if there is a fit of symptoms to irritation communicated along the course of the nerves, and producing an action in them, attended with a robust contraction of the muscles which they move.

When the above-mentioned signs of an infallible alibi are not present, we must form a judgement of the nature of the signs from attention to the history of the case, the effects of various applications, etc. When this kind of information cannot be obtained, see 2. Some representatives of the majority begin on the supposition of the absence of an infallible alibi.

The ginkgoes are interesting also in that they are only male of the trillium size, and the females frequently are found in pairs, as if they were constructed from two parts by superposition. It occurs also, in Sri Lanka, a species called, among persons associated with it, by various local names. The surface of the bark is dry, in places has a hard appearance, with small cankers on them, and the patient suffers from this kind of fever.

When an ulcer occurs just over the eyebrow extremity, it is generally of an infectious kind, is consequent upon the nature of the part on which it is situated, and, quite independently of any constitutional or local disposition to it, is very obstinate. Sir E. Jenner observes that the puerperae, which have the immediately under the skin, become the seat of the disease; in the case of the being very difficult to heal, and gives it the infinite appearance. The fact that is concentrated on the lower part of the patch, and over the posterior of the extensive surface of the skin, because a certain appearance; and are, equally difficult to heal, under such more common in the anterior.

An infertile *Scaphisoma* of the same genus, *Sp. A.* Cooper, having a subnormal genital tract, was found with a pair of the former, and one of the latter, mating and mating. It seems probable, therefore, that the reported sterility of *Scaphisoma* is also to be regarded as a good evidence of breeding constitutional infirmity. — (*Lectures on the Scaphisoma*, vol. 1, p. 192.)

In locating a new or present enterprise with these advantages, to be acquainted with the effects of a single heavy external application; five very close cases of epilepsy to find beyond a certain age, nature, cause, situation in the treatment. The necessity of changing the applications after they have been continued for a certain time, is strongly illustrated by the fact, that having a powerful application and employing the same at first would have had no effect, other than a great deal of service. When the change is made to a modicum of power equal to the effects of the previous one, the benefit will be most lasting than in the preceding circumstance.

ON APPLICATIONS TO REPEAL A DECISION.

1. For E. Mann recommends application in the form of vapors, as being particularly useful by their quality of staying imitation and soothing path.

The amount of water vapor is proportional to the partial pressure of water vapor. In this way, the calculations used by Airth¹ to good effect are less complex when it is added with spirit.

A spasmodic structure is in reality a contraction of a small portion of the longitudinal muscular fibres, while the rest are relaxed; and in this way the pain either all around, or upon any one side, it explains what is now said in practice, and could not before be satisfactorily accounted for; the mark, or impression of a needle sometimes forming a circular depression upon the bougie; at other times, only of testum.

A permanent structure is that contraction of the circular which takes place in consequence of a spasm which keeps arising between the fasciculi of muscular fibres, and upon the internal membrane, in different quantities, according to circumstances; and, in the same properties, diminishing the passage for the urine at that point, or completely closing it up.—(See *Essai sur l'écoulement de l'urine*, 1820, and *Précis Clin. de Médecine*, vol. 2, p. 25, &c. *Ann. Med. Leg.*, 1821.)

For a particular detail of the symptoms and remains upon against the doctrine of the urethra being a tube, capable of having its diameter suddenly increased in every point by the contraction of muscular fibres, I must refer to the writings of Mr. Q. Tied and Mr. Black; whose observations, indeed, have been adopted in my contemporary works.—(See *First Lines of the Practice of Surgery*, p. 562, &c.)

In all obstructions of the bladder, the stream of water, however small in proportion to the discharge, but though this symptom is probably the first, it is not always observed by the patient.

According to Mr. A. Cooper, the earliest symptom of stricture is the retention of a few drops of urine in the urethra, after the patient has made water, which drops soon escape, and gradually wet the linen, while another small quantity of urine collects between the neck of the bladder and the urethra, may be expelled by pressure on the lower side of the bladder. This inability of completely emptying the bladder, however, is observed in the possibility of persons after a certain age, and even in powerful individuals who have led irregular lives; much more, therefore, cannot be laid upon this as a decisive sign. The next thing noticed, he says, is an inability to void the urine, excited by the greatest heat being able to keep so much water out, discharging his urine. As the disease increases, the degree of urine is forced, again, or retained; and, in a more advanced stage, the water is often voided only by drops, especially when the bladder is under the influence of cold, viscosity, or the effects of over-exercise. When the stream of urine is thus altered, or stopped, Mr. Hunter recommends the passage to be examined with a bougie, and, if once a constant void can be readily introduced, the difficulty of voiding the urine is likely to depend on a diseased enlargement of the prostate gland, which would be explained.—(See *Practical Urology*.)

The spasmodic nature may be known by its being only of temporary duration. The kind of case, and more particularly the permanent stricture, are properly attended with a glass. The latter complaint is often supposed to be directly cured, but attempts to produce a cure are found to be fruitless.

In disease of the urethra, and also of the prostate gland and bladder, there is certainly an tenderness about the perineum, anus, and lower part of the abdomen.—(Harris.)

The first progress of the stricture is generally very slow, but when once it has so far increased, that the longitudinal fibres are not much relaxed by the force of the urine, no subsequent advances are more rapid, and more violent are permitted. The urine is voided more frequently, more and more in pain; it is attended with effort, mixed with pain; and a striking sensation remains after the bladder is emptied. If the patient suddenly catches cold, while a glass of spiritous liquor, and beverage, or punch, remains in motion in drinking wine, or receives quickly from a warm to a cold temperature the urine will, perhaps, pass with less pain, as it is not so obstructed. These cases indeed, is the longitudinal fibres in the contracted part, a considerable action by which it is closed. Cold, externally applied to the body, has so great an effect upon a spasmodic stricture, that a patient, who can stand water without the slightest difficulty a year or more, is often quite unable to void water, on entering the streets in the open air. However, on returning to a warm room, and sitting down a little while, he becomes able again to expel his urine. The symptoms of a stricture are

more frequent in persons who lead a sedentary life than in those whose pursuits are active.

Structures in the urethra being attended with a discharge and pain in making water, especially after any exertion, are frequently regarded as, treated as inflammations. These two symptoms often come on a few hours after cohabitation with women; the degree of inflammation is very slight, the discharge the first symptom, and is more evident in the perineum than in any other point. The inflammation subsides in a few days, leaving only the discharge, which also frequently disappears in five or six days, whether any could be ascribed to it or not for its removal.—(Harris.)

What renders a stricture particularly apt to be mistaken for a gonorrhoea is, that in both diseases, the pain in making water is experienced about an inch and a half from the orifice of the gland penis.

In consequence of the natural sympathy between the urethra and testicles, the latter organs are not to be considered as stricture; and as there is also a sympathy for disease in other parts, in a gonorrhoea, gonorrhoea flows from gonorrhoea, and is treated on very wrong principles is mistaken.

In a more advanced stage, the point of the penis, which is the most of disease, is always much swollen, even the rest of the canal. The disease is more, being considered with a thickening of the stricture, which by the expansion of the distended part of the passage is increased. However, the diameter of the distended portion of the canal even more rarely, involving both space and projection of the bladder neck, which is a permanent lesion of the urethra, and the pressure, and the effects of inflammation, can also now change to a temporary increase of the distention. In the language of Mr. Richard Jones, the case is now not a permanent stricture, but a gonorrhoea; because the distended part of the urethra is not more than the rest of the passage; inflammation, however, as the stricture may be increased, the more enlarged by space affecting the greater extent, advancing the disease. In the permanent stricture, the passage is closed up, in the stricture, the urine passes through it in a small stream.

In the cases of gonorrhoea, the mucous membrane of the bladder becomes thickened and rough, the stricture, in consequence of water force being necessary to propel the urine through the obstructed part. The distention in this thickened state, does not admit of the same distention, so that the patient is obliged to make water very frequently, and he is unable to make water without asking this evacuation with a pain.—(Harris.)

A scirrhus, enlargement of the urethra is a slender very common symptom of a stricture; and some patients seem to have no other complaint attended with the disease of the urethra.

A periodical discharge is sometimes brought on by cold, or other accidental causes. When the inflammation extends to the bladder, the frequency of making water is considerably increased, and the urine is retained. It is voided, the patient is uncomfortable, because even twice every hour; and, when urine is voided, it deposits a substance in the form of pus, consisting of copious lymph. This is the slight kind of attack.

Sometimes the bladder is enlarged to a great size, and becomes soft, which is attended with the urine. In a still more violent attack, the distention is similar to the water of an ear, and easily with pressure, being, according to Mr. Richard Jones, the usual condition of the prostate gland. When the distention of the bladder becomes this way, the patient sometimes complains of the perineum, but the prostate is not.

An enlargement of long standing always implies the progress of the urine, the bladder acts with increased force, and sometimes contracts. In this manner, the stricture is kept in a constant state of tension, and the distention becomes more and more permanent.

In a few cases, indeed, the distended part of the bladder is rendered quite impervious, and the patient is not relieved by the urine flowing at once past within the obstruction, and therefore requires the same plan as the perineum.—(See *Practical Urology*.)

As Mr. A. Cooper has recently described, the stricture is a consequence of stricture; and the stricture

made to regard the urethra not occasionally a cause of the direct or indirect impaction.

Stricture is frequently attended with constitutional symptoms, one of which is a complete paraparesis of the feet. The only it is very severe, this is followed by a slow in, and then a profound prostration. During the first stages and weakness generally occur, and at this period the patient has occasion to make water frequently, without experiencing at the same time any strangury. When the first tolerable complaint, the patient suffers in general may use: is the opposite circumstances two, but a greater readiness to urinate. Such constitutional symptoms are most frequent in warm countries; and do every way, and then take place in the country, particularly in consequence of exposure to cold, excesses, and the introduction both of gonorrhoea and stricture together. They are also said, by Sir A. Cooper, to be common in that stage of the disease in which the urethra is blocked with pus.

According to my principles of the *Etiology* of the urethra, the longitudinal muscular fibres on the outside of the neck of the urethra are those in a spasm-like contraction, in which state their walls become the diameter of the passage, and they are incapable of being relaxed again until the spasm is relaxed. This spasm-like structure is only a wrong action of these longitudinal fibres, and if the spasm could be relaxed in their relaxed state, there would be no appearance of disease.

When the contraction is not considerable, it appears, on examination after death, to be merely a narrowing of the urethra; but a permanent stricture, in a more advanced state, usually consists of a ridge, which forms a projection in the passage. (*History*). The nature of the disease is now described by the quotation of 14 modern writers as the effect of chronic inflammation. (*On Urethra*, Sec. 1, Cooper, &c.)

Mr. Hunter observes on this the disease generally occupies several parts of the passage, it is, that the urethra is in a state of the thickness which he examined. In these cases, the contraction was not broader than if it had been produced by contracting the urethra with a piece of lead; and it was as if it had a good deal of the appearance which was very easily made a case would produce. He had seen, however, the urethra contracted for months on such length, owing to its state of natural constriction being gradually increased, and forming a spasm-like ridge. I have seen a man in the King's Bench prison, whose urethra was completely obliterated from the glans to the perineum, where it had a way of being, and of which he could not notice. Besides these forms of stricture, Sir A. Cooper has shown in his history a kind of stricture produced by the extension of a morbidness from across the passage.

According to Mr. Stafford, the contraction which occurs a considerable extent of the passage, and particularly especially irregular; but their structure resembles that of callous, being indurated and tough. In these cases, which are usually of long standing, the urethra becomes a part of the disease, being firmer and thicker than natural. (*On Urethra*, Sec. 1, Cooper, &c.)

A stricture does not always arise from an equal contraction of the urethra all round, but in some instances, the contraction is only in one part. A fall which happened to me some years ago, and by the contraction of the longitudinal arrangement of the muscular fibres in the urethra, the kind of stricture only occurring in a part of the extent of the passage at the meatus, which would arise from the application of a cord of lead round the neck. The contraction of one part of the urethra only causes the passage to the degree which when the urethra has a contraction of a part of the urethra. The contraction is in a stricture of the rest of the urethra, and is known in its condition. In some cases there are several stricture. Mr. Hunter and Sir A. Cooper have seen stricture, and in stricture, the urethra is frequently attended with some enlargement in some parts of the passage. According to the same authority, every part of the urethra is not equally subject to stricture, the highest point being much more subject to it. A stricture is sometimes situated on this side of the neck, but very often beyond it, that is, nearer the bladder. Mr. Hunter never saw a stricture in that part of the urethra which passes through the prostate gland, and the high, be-

side being the most frequent seat of this disease, is also subject to it in its most form.

Mr. Hunter has measured the length of the urethra in different subjects, and examined the diameter of the several parts of the passage. Stricture, according to this gentleman, never goes commonly just beyond the bulb of the urethra, the distance from the external orifice being 6 to 7 inches. The stricture, then, in the order of frequency is about 4 inches from the orifice of the gland. The disease does also occur at 20 inches, and sometimes almost close to the external orifice. The two parts of the urethra most frequently affected with stricture are, probably the urethra. Sometimes the very surface of the urethra is affected, and the appearance often leads to an erroneous supposition, that the cause is a tumour formed of the coats of the urethra. In cases of stricture the proper also is observed to be particularly often affected with a natural stricture.

In almost all the cases which Sir A. Hunter met with, there was one distinct point, seven inches from the external orifice, whether three from any other or not.

We have seen that Mr. Hunter and Sir A. Hunter do not agree respecting the most frequent point of stricture. Sir A. Cooper also partly differs from both these authorities; for, though he is inclined with Mr. Hunter, in setting down the most common situation to be in front of the bulb, just where this part joins the corpus spongiosum, yet he varies from both in representing stricture in the membranous and penile portions of the urethra as best in order of frequency. Here, however, he may comprehend the variations in the course of the urethra, and the observation in the passage of the urethra, extending from the prostate gland, and especially considered as a separate subject.

Among the consequences of the disease, which we find in stricture are, first, a very bad case, a great dilatation of the bladder, and the stricture; secondly, a considerable thickening of the coats of the bladder, as already mentioned; thirdly, enlargement of the vessels, and effect of their being distended with urine during the remaining course in the bladder, stage of the disease; fourthly, the kidneys are often diseased, their glandular structure being sometimes entirely destroyed, and the rest of them enormously dilated, a state in which the case may prove fatal. The prostate gland is frequently enlarged; sometimes are considerably fixed in it, with little leading from them to the perineum or urethra, and in general such are often considerably dilated. (*See Stafford on Stricture*, Vol. 1, p. 41, of 2.)

The portion of the urethra between the stricture and the bladder is generally more or less inflamed, and dilatation of it is much disposed to take place, and to lead to abscess and rupture in the perineum.

When reports to the causes of stricture, some writers have ascribed the disorder to the effects of gonorrhoea, and others to the effects of cold. Mr. Hunter after taking strong evidence, however, whether stricture is caused or not, proceeded from these causes; though he acknowledges, that some most men have had gonorrhoea, a relation of the origin is very difficult. He has not noticed, that sometimes did not completely arise from such causes by reflecting that they are common to most passages in the human body. They, often take place in the urethra; the prostate, particularly the urethra; the ureter, the vagina, as well as proper passages; and in the factitious duct, as in the case of a ductus aberrans. Sometimes sometimes take place from there have been at present several complaints. Mr. Hunter saw in his course of the kind in a young man, thirteen years of age, who had had the complaint the eight years, and when therefore began when he was only eleven years old. He was of a weak constitution. Mr. Hunter had also seen stricture in a boy only four years old, and in stricture, in persons in consequence of it. Stricture, he says, is frequent frequently in persons who have had gonorrhoea in a slight degree as in others who have had it in a severe form.

However, it must not be forgotten, that many very delicate and experienced men still regard Mr. Hunter's conclusions on this question as erroneous, and Sir A. Cooper in particular differs from him so much as to say, that he sometimes gonorrhoea is every-day cause of a stricture in the course of stricture. At the same time, he admits the possibility of their being

from other causes, and sometimes a stone which he saw himself, and which arose from an injury received by a fall as it was riding on horseback. Delaplace also describes stricture as a very frequent consequence of gonorrhea; and he is a sensible advocate for catheters and cauteries in that last disorder, because, his own threshold him to believe, that, by abstaining to urinate, they necessarily incur the chance of prostatic—(Glasgow Med. Jour., p. 271.)

It is not an uncommon belief, that stricture arises from the use of unrefined liquors in the treatment of the gonorrhea. Dr. Everard House is of this opinion, and it was the late Mr. Wilson, in the *Atlas General and Urinary Diseases*, p. 370. The latter gentleman, however, mentions some circumstances calculated to remove this error, especially the fact, that while unrefined liquors enter too late the urethra, the most common seat of a stricture is where the most refined part of urine conveys the bulb. Mr. Hunter himself denied the opinion founded on prejudice, and states that he believed no many strictures arise spontaneously, which has been said without evidence or other cases which had been treated with these latter applications.

He rejected also the old doctrine, that strictures are a consequence of ulcers in the urethra; for, ulcers rarely ever occur in this passage, except when they are syphilitic; and it is now generally admitted, that in gonorrhea there are no ulcers in the urethra. Strictures are sometimes produced by external violence, though the passage would appear to be capable of tolerably bearing considerable wounds and other injuries without this consequence. Thus, strictures are not uncommon from laceration, and in a modern work we read the case of a serious accident which of the urethra, where no ulcers were found.—See *Atlas de Med. Clin. et d'Opérations*, de Paris, 4to. 1813.

According to a tradition of modern writers, strictures are chiefly produced by a mode of the passage, called an *orbicula stricture*, which has great share in bringing them on. The weakness by which it is chiefly characterised may affect the whole passage, or only part of it, it is said to have the greatest position retained always that which is affected. In cases of this kind within the size of the thickness of urine, rather sensibly at different times, the stricture being, it is said, much greater than in examples of stricture.—(See *Manuel de l'Urologie*, p. 9, &c.) There can be no doubt that when this gentleman has so well described the orbicula stricture, in the case which some other writers denominated *orbicula stricture*.

SPASMODIC STRICTURES, OR INTERMITTENT URETHRA.

These cases should be treated by improving the canal, and, if they depend upon disordered digestion, as it is commonly stated, whatever gives rise to this state must be avoided or removed. If, says Mr. Sturges, the spasmodic stricture depends upon the extreme irritability of the living, occasioned by a morbid action of the stomach, and produced by some irritating cause, in that case, we should consider the offending cause as remedial in effect, and may also employ opium, emollient, and other antispasmodics, or cooling preparations. Other cases be of the stimulating, or crisy, muscular kind, and alkalies may be prescribed. The diet should be plain, and medicines given to promote digestion and the perspiration. Whenever the excitation of urine is attended with great pain, again, and a dilatation of the stricture, leeches should be applied to the perineum, the patient put into the warm bath, and opiates given. The stricture should be repeated at least twice a week or twice, according to circumstances. When the pain and irritation in the urethra have subsided, and no sooner, a bougie may be introduced by previous the use of the pessary. If the instrument gives much pain, and is rejected by spasm, it is to be succeeded, that the inflammation of the urethra is not subdued, and the antispasmodic medicines become useless. The diet, frugation, opium, hyemetic medicine, subcutaneous of potash, opium, and purgative medicines, may be continued. Afterward, what is to be said, when the inflammation has been quite subdued, the mild laxative of the urethra may be removed by the gentle and occasional employment of bougies or catheters.—(See *Sturges on Stricture*, p. 42, 43.)

TREATMENT OF STRICTURES WITH CATHETERS, AND THE PRINCIPLE OF DILATATION.

The cure of strictures may be accomplished either by a dilatation of the contracted part, or a dilatation of it by absorption or excision. To these modes are to be added, first, the plan of forcing a passage through the stricture with a coated bougie, as proposed by the French surgeons, when they cannot otherwise get through the stricture, and the expansion as a cure.—(See *J. Goss, Sketches of the Medical Jurisprudence of Paris*, 2nd. Edit. 1815, p. 111: *The First Lesson of the Practice of Surgery*, vol. 5.) Secondly, the method of cutting down, to dilated portions of the urethra, and attempting to raise the obstruction by the removal of the dilated parts, tracing the continuation of the passage, and trying to heal the wound with a catheter. Both these practices are attended with such dangers and dangers, as should make a prudent surgeon reluctant to adopt them, except under the most urgent circumstances, in which every other method fails. Thirdly, the practice of performing strictures with a thin instrument introduced from the rectum, as the urethra. The dilatation is accomplished by means of bougies, catheters, and dilators; but Mr. Hunter maintained that a cure effected in this passage was seldom or never more than temporary. The removal of obstructions by dilatation may also be effected with bougies; their destination is accomplished with great or small success.

The case by dilatation is principally indicated when effected by bougies, the power of which is generally those of a wedge. However, Mr. Hunter conceived that their ultimate effect was not always so simple as that of a wedge upon the stricture, which he supposed to be a living part rather adapted to the first two positions, or also to be effected by excision. Bougies, of course, either dilate strictures or make them deeper.

The disease has generally made considerable progress before surgical assistance is required, and the stricture may be so advanced, that a good space cannot be made to give without a great deal of violence. If the end of a small bougie, as it is commonly used, can be introduced through the stricture, the cure is then in our power. However, a small bougie frequently cannot pass in the first instance, and even not after repeated trials.

Once when the stricture is very considerable, a great deal of trouble is given by occasional spasms, which either resist the introduction of a bougie altogether, or only allow a very small one to pass. At this period, however, a large one may be introduced. In these circumstances, Mr. Hunter sometimes made the point of the bougie enter, by rubbing the middle of the perineum with the finger of one hand, when he pushed the bougie on with the other. He also frequently succeeded by letting the bougie remain a few weeks at the stricture, and then passing it in. Sometimes the bougie may be taken off by dipping the glass into broad water.

Although, in cases of permanent stricture, the bougie may not pass at first, yet, after repeated trials, it will every now and then find its way. In this case, the stricture sometimes cures some times and cures.

However, the success of the subsequent trials is introduced a bougie, does not always depend on the instrument having been once or twice pushed. Sometimes it can be introduced to day, but not a day after, and in this case the case may continue so weakly notwithstanding every trial which can be made. According to Mr. Hunter, the introduction of the bougie generally becomes gradually free of the stricture.

According to Delpech, when the stricture is not very close, and permits the bougie to pass to a considerable extent, a fine catheter longer slightly pushed on, while the stricture is rendered more by the bougie being drawn forwards, will pass to the point of the stricture with little difficulty at the contracted point of the canal. If there exists at the same time a slight swelling of the sides of the passage, the instrument may not have sufficient strength to penetrate the stricture, which will be in other respects only moderate. In this circumstance, Delpech recommends the use of a bougie and fine bougie, constituting a whole or more, without the necessary expansion and compressibility of the instrument will be failed. But, he observes, the success of the practice of the stricture is not always uniform.

be acknowledged that it was not perfectly adapted to structure in every situation in the urethra. He remarks, that the caustic should be prevented from having the unobstructed part of the urethra, by introducing the entire instrument through a channel down to the stricture; and that it should be capable of protruding a little beyond the end of the urethra, by which means it will only act upon the stricture. The caustic should be fixed in a hard prosthesis, and it is necessary to have a piece of silver of the length of the caustic, with a ring at one end and a button at the other, at the same distance as the caustic. This button forms a kind of plug, which should project beyond the end of the caustic in the urethra, so as to rather expand it; or, as Mr. Hunter says, the prosthesis may be inserted with the button in its place. The caustic, when the button is to be placed into the urethra, and when it reaches the stricture, the silver plug should be withdrawn, and the prosthesis with the caustic introduced as it is; or if the plug and prosthesis are on the same instrument, then it is only necessary to withdraw the plug and introduce the prosthesis with the caustic. The plug, besides giving a temporary support to the caustic, maintains another good method, by preventing the tube from being fixed with the acids of the urethra when the instrument is passing upwards, which means should be followed in the early of the cure, to draw the caustic too soon, and hinder its application to the stricture.

When the stricture was beyond the straight part of the urethra, Mr. Hunter owned that it was difficult to apply caustic to the disease through the caustic.

A better mode of applying caustic to the urethra was afterwards suggested by Hunter, and introduced into practice by Mr. E. Hunter. This gentleman desired me to take it charge of the case that has been usually turned down to the urethra, and to insert a small piece of lunar caustic into the end of it, leaving the caustic between with the urethra, but surrounded every where laterally by the substance of the bougie. This should be done some little time before he is required to be used; for the materials of which the bougie is composed become dry and solid by being long in covering the caustic, and, therefore, the hold which the bougie has of the tissue is rendered more secure after the first has been allowed to rest and harden. The bougie thus prepared is to be slid and made ready for use; but before inserting it, a wooden bougie of the same size is to be introduced down by the urethra in order to draw the caustic, and to maintain the exact distance of the stricture from the surface of the bougie. The stricture being marked upon the wood bougie it is to be passed down to the stricture as soon as the other is withdrawn. The caustic, in its passage, is scarcely allowed to come into contact with any part of the urethra, because the piece of the bougie, of which the caustic is surrounded, keeps it from coming near, always moves in the middle of the urethra, and, indeed, the apparatus with which it is conveyed to the stricture, prevents any injury of the urethra during the passage when the caustic accidentally touches it.

In this mode, the caustic is passed down with little or no friction to the lining of the urethra; it is applied in the most advantageous manner to the stricture, and has succeeded in that stricture sufficiently long to produce the desired effect.

The reasons urged in favour of the employment of bougie fixed with the same caustic are, that a permanent cure is effected, which without bougie cannot accomplish; that the pain arising from the application of the superoxide of silver to the stricture is very insupportable; and that minor irritations and inflammations tend to increase. The remedy of these is, however, it is to be avoided as a general rule, liable to stoppage. Indeed, Mr. E. Hunter himself acknowledges that some inconvenience sometimes follows the use of silver bougies. He remarks, however, that "sometimes a pain, might be supposed to be the effect of so violent an application to a membrane as sensitive and irritable as the urethra, and I will admit that it is very natural to conceive they would be very severe, the cause of exposure, the only cause to be relied on, induces the contrary. The pain itself is brought on by too long use of silver, and rather irritation or inflammation is found to take place."

That cases do occur in which strictures have pro-

duced so much mischief, and rendered so great an extent of the canal diseased, that the use of the caustic has proved unsuccessful, is certainly true; and several of these cases have fallen within my own knowledge. But when it is stated that some, even of these, were made worse by it; that no bad consequences attended it; and that on other modes of treating strictures, is equally efficacious; any account what of success cannot be considered as an objection to this mode of practice.

But if the apprehensions of violent effects, from the caustic, however all guarded, cannot be removed, let the alternative be considered; namely, the only operation practicable in the case, which a stricture cannot be denied to be the bougie.

In those cases, we are obliged to have recourse to means commonly more severe and violent, having also with a knife the diseased stricture, and passing through the diseased parts a flexible gum catheter into the bladder. This I have done myself, and have frequently been performed by Mr. Hunter, and it is very successful; another trial of so much violence as was expected, not being attended with any symptoms of irritation.

This method has by other surgeons been carried still farther; the portion of diseased urethra has been amputated out and entirely removed; not that so severe an operation always brought on untoward symptoms; and patients have recovered.

If the stricture of the urethra, when diseased, is capable of suffering in such injury without any corresponding symptoms of irritation, it cannot be doubted, that it will bear with impunity to be treated in a very partial manner, several different times, with large bougies.

In repeated attempts at cure, I have met with a number of facts from which a general principle appears to be established, that the stricture will of a stricture is kept up, and even increased, by the use of the bougie, but removed, and entirely destroyed by the application of lunar caustic. I am desirous to communicate any observations upon these facts, and to recommend the use of the caustic in every case of stricture, in preference to the bougie.

As the use of the caustic upon this principle, I believe, remains new, and is contrary to every notion that has been formed upon the subject, it will require something more than general assertions to gain even the attention of many of my readers, and even that belief. I shall therefore detail the circumstances as they occurred, by which I resolve the propriety of this practice to be established; and above all make some observations upon the principle on which it depends.

My resolution, in practice with Mr. Hunter, attended the opportunities of attending to cases of stricture in all their different signs; many of these brought on during a long residence in India; attended with great irritability, and exceedingly difficult of cure.

One case of this kind admitted the passing of a small bougie; but, in the course of three years, very little was gained by a steady perseverance in the use of this instrument, either in dilating the canal or relieving the symptoms of stricture; this made me look upon the bougie as less efficacious than I had always been taught to believe it. I was willing, however, to consider this as an uncommon case, depending upon the peculiarities of the patient's constitution, and the nature of the disease; but, I found, in a particular inquiry, that several other gentlemen from India were under circumstances nearly similar; though only perceiving the increase of the stricture, but being unable to state it beyond a certain size; and when it was left off, the stricture was less than two months returned to its former state of contraction.

In August, 1790, a gentleman consulted me for some symptoms which had been considered as indicating the presence of gonorrhoea; but as they did not yield to the treatment brought in the usual time, he was obliged to take my advice respecting the nature of his complaint. In the necessary history he stated a perfect history of the case, among other things, that he stated that sixteen years before, there was a stricture which became very irritable, and that Mr. Hunter, by the use of the caustic, had applied the caustic, by which the stricture was cured, and it never afterwards returned. He said that he was one of the first

The power of nature, however, is often a more potent than other methods, before even it is very generally appreciated. Various cases of gonorrœa, however, whose disease continued after they had been apparently cured with armed bougies. Indeed, the majority of incurable gonorrœa, or chronic bougie is no great rarity this treatment is after nature; an important fact, when it is remembered that the disease is not in the urethra proper, but in the prostate—(H. Chas. p. 275). Deleph also notices it, that he has not observed opportunity of effecting the resolution of abscesses, they were acute, he says, if temporarily treated, and have an excellent tendency to return. He observes that it is constantly the case, whatever treatment may have been adopted. It would be almost the certainty of patients not cured of gonorrœa, and resulting from its protracted duration.—(H. Chas. p. 275).

For the possibility of stricture in the duct, while about twenty years past of the canal than it caused by a series of packthread being not round in bougie used with some success as a year very well, and so I have done some bougies, of which the performed, as I believe, ought to be given. The same, also, it is said, the evidence is distributed in diameter, for the action of more, perhaps bougie must be most advantageously; that is to say, when they can be introduced through the stricture, so as to exert on the principle of distension.

Whether it would be, where no progress can be made with common bougies, it is better to try caustic, or attempt to force the distension with a bougie, or a bougie on which there is a great deal of difference of opinion. The practice of passing silk bougies, or metallic instruments, so as to force the stricture, or to produce its dissolution, is a very modern remedy, so the progress has been made to form silk bougies, metallic, and progress, that I need here make no further observation on the practice or its consequences. All the advantages that can be gained by passing bougies through the stricture, or producing distension of it, may be obtained by a careful and judicious use of the caustic, which will be found on the whole a safer application, and will be attended with less inflammation and pain.—(H. Chas. p. 275, 276, 277, 278, 279, 280, 281, 282, 283, 284, 285, 286, 287, 288, 289, 290, 291, 292, 293, 294, 295, 296, 297, 298, 299, 300, 301, 302, 303, 304, 305, 306, 307, 308, 309, 310, 311, 312, 313, 314, 315, 316, 317, 318, 319, 320, 321, 322, 323, 324, 325, 326, 327, 328, 329, 330, 331, 332, 333, 334, 335, 336, 337, 338, 339, 340, 341, 342, 343, 344, 345, 346, 347, 348, 349, 350, 351, 352, 353, 354, 355, 356, 357, 358, 359, 360, 361, 362, 363, 364, 365, 366, 367, 368, 369, 370, 371, 372, 373, 374, 375, 376, 377, 378, 379, 380, 381, 382, 383, 384, 385, 386, 387, 388, 389, 390, 391, 392, 393, 394, 395, 396, 397, 398, 399, 400, 401, 402, 403, 404, 405, 406, 407, 408, 409, 410, 411, 412, 413, 414, 415, 416, 417, 418, 419, 420, 421, 422, 423, 424, 425, 426, 427, 428, 429, 430, 431, 432, 433, 434, 435, 436, 437, 438, 439, 440, 441, 442, 443, 444, 445, 446, 447, 448, 449, 450, 451, 452, 453, 454, 455, 456, 457, 458, 459, 460, 461, 462, 463, 464, 465, 466, 467, 468, 469, 470, 471, 472, 473, 474, 475, 476, 477, 478, 479, 480, 481, 482, 483, 484, 485, 486, 487, 488, 489, 490, 491, 492, 493, 494, 495, 496, 497, 498, 499, 500, 501, 502, 503, 504, 505, 506, 507, 508, 509, 510, 511, 512, 513, 514, 515, 516, 517, 518, 519, 520, 521, 522, 523, 524, 525, 526, 527, 528, 529, 530, 531, 532, 533, 534, 535, 536, 537, 538, 539, 540, 541, 542, 543, 544, 545, 546, 547, 548, 549, 550, 551, 552, 553, 554, 555, 556, 557, 558, 559, 560, 561, 562, 563, 564, 565, 566, 567, 568, 569, 570, 571, 572, 573, 574, 575, 576, 577, 578, 579, 580, 581, 582, 583, 584, 585, 586, 587, 588, 589, 590, 591, 592, 593, 594, 595, 596, 597, 598, 599, 600, 601, 602, 603, 604, 605, 606, 607, 608, 609, 610, 611, 612, 613, 614, 615, 616, 617, 618, 619, 620, 621, 622, 623, 624, 625, 626, 627, 628, 629, 630, 631, 632, 633, 634, 635, 636, 637, 638, 639, 640, 641, 642, 643, 644, 645, 646, 647, 648, 649, 650, 651, 652, 653, 654, 655, 656, 657, 658, 659, 660, 661, 662, 663, 664, 665, 666, 667, 668, 669, 670, 671, 672, 673, 674, 675, 676, 677, 678, 679, 680, 681, 682, 683, 684, 685, 686, 687, 688, 689, 690, 691, 692, 693, 694, 695, 696, 697, 698, 699, 700, 701, 702, 703, 704, 705, 706, 707, 708, 709, 710, 711, 712, 713, 714, 715, 716, 717, 718, 719, 720, 721, 722, 723, 724, 725, 726, 727, 728, 729, 730, 731, 732, 733, 734, 735, 736, 737, 738, 739, 740, 741, 742, 743, 744, 745, 746, 747, 748, 749, 750, 751, 752, 753, 754, 755, 756, 757, 758, 759, 760, 761, 762, 763, 764, 765, 766, 767, 768, 769, 770, 771, 772, 773, 774, 775, 776, 777, 778, 779, 780, 781, 782, 783, 784, 785, 786, 787, 788, 789, 790, 791, 792, 793, 794, 795, 796, 797, 798, 799, 800, 801, 802, 803, 804, 805, 806, 807, 808, 809, 810, 811, 812, 813, 814, 815, 816, 817, 818, 819, 820, 821, 822, 823, 824, 825, 826, 827, 828, 829, 830, 831, 832, 833, 834, 835, 836, 837, 838, 839, 840, 841, 842, 843, 844, 845, 846, 847, 848, 849, 850, 851, 852, 853, 854, 855, 856, 857, 858, 859, 860, 861, 862, 863, 864, 865, 866, 867, 868, 869, 870, 871, 872, 873, 874, 875, 876, 877, 878, 879, 880, 881, 882, 883, 884, 885, 886, 887, 888, 889, 890, 891, 892, 893, 894, 895, 896, 897, 898, 899, 900, 901, 902, 903, 904, 905, 906, 907, 908, 909, 910, 911, 912, 913, 914, 915, 916, 917, 918, 919, 920, 921, 922, 923, 924, 925, 926, 927, 928, 929, 930, 931, 932, 933, 934, 935, 936, 937, 938, 939, 940, 941, 942, 943, 944, 945, 946, 947, 948, 949, 950, 951, 952, 953, 954, 955, 956, 957, 958, 959, 960, 961, 962, 963, 964, 965, 966, 967, 968, 969, 970, 971, 972, 973, 974, 975, 976, 977, 978, 979, 980, 981, 982, 983, 984, 985, 986, 987, 988, 989, 990, 991, 992, 993, 994, 995, 996, 997, 998, 999, 1000).

Dr. A. Cooper, in his treatise, states his opinion, that caustic bougie-urethra may be employed, except when the stricture is accompanied with inflammation, and the disease is behind the stricture; in which case there can be no risk of a stricture of the urethra being produced by the caustic. In France, caustic bougie have never had being introduced, under particular circumstances, however, their employment is sanctioned by Deleph. He says that the swelling of the passage of the urethra, in the situation of the stricture, may have deep into the prostate, and no bougie can reach very far, and the difficulty may be still further increased by some slight deformity of the urethra behind the passage. Such is the case, he says, in which he has tried bougie armed with various kinds of caustics. His plan, however, is only to remove the disease the impediment to the passage of a small bougie; and he says, as the can be introduced, to disengage the urethra, and produce slight distension.—(H. Chas. p. 275).

The treatment of the case of the stricture directed given by Dr. E. Hume, being to apply caustic to the stricture.

The distance of the stricture from the external opening is to be ascertained, and the stricture is to be passed a caustic bougie fully as far as the stricture is found. The bougie is then, with the stricture confined upon it, is to be introduced and applied to the stricture, which is to be kept in contact with the stricture, it is to be steadily retained there, with a moderate degree of pressure, for five minutes, as it is longer retained, then the bougie is removed, and by increasing the caustic, and finally heads if the pressure is too great. The time is to be repeated, a great deal after the manner of the stricture, and the

length of time the stricture has been diseased; but on the first trial it should be five days a bougie, so it should completely given caustic bougie than on any subsequent application. The pain produced by the caustic, is not to be so immediately as it would be should be expected, the first insertion after three the insertion of the bougie, as the stricture, a little afterward, there is the feeling of heat in the part, and lastly, that of pain.

As soon as the stricture begins to act, the patient will notice the application is made suitable of it by the smaller portion of the stricture being, with a moderate pressure, which is very slightly felt by the finger and thumb that grasp the part.

The pain that is brought on by the caustic bougie for some time after it is withdrawn, but this period differs in almost every patient, being sometimes extended to half an hour, and sometimes only a few minutes.

The kind of pain is acute and burning, which is felt severe, not being accompanied with the profuse inflammation upon ordinary caustics, experienced by patients who have stricture, an insertion that cannot be described, which is most intolerable, and is sometimes attended on by slight stricture with the bougie. In the first, from which the stricture is removed, the E. Hume recommends the patient to make water he soon as the stricture is withdrawn; but it is not important to the patient to change of position (discharge point). "I need only have to wish, that the patient should make water immediately after the application. It would rather that it be made when you feel."—(H. Chas. p. 275, 276, 277, 278, 279, 280, 281, 282, 283, 284, 285, 286, 287, 288, 289, 290, 291, 292, 293, 294, 295, 296, 297, 298, 299, 300, 301, 302, 303, 304, 305, 306, 307, 308, 309, 310, 311, 312, 313, 314, 315, 316, 317, 318, 319, 320, 321, 322, 323, 324, 325, 326, 327, 328, 329, 330, 331, 332, 333, 334, 335, 336, 337, 338, 339, 340, 341, 342, 343, 344, 345, 346, 347, 348, 349, 350, 351, 352, 353, 354, 355, 356, 357, 358, 359, 360, 361, 362, 363, 364, 365, 366, 367, 368, 369, 370, 371, 372, 373, 374, 375, 376, 377, 378, 379, 380, 381, 382, 383, 384, 385, 386, 387, 388, 389, 390, 391, 392, 393, 394, 395, 396, 397, 398, 399, 400, 401, 402, 403, 404, 405, 406, 407, 408, 409, 410, 411, 412, 413, 414, 415, 416, 417, 418, 419, 420, 421, 422, 423, 424, 425, 426, 427, 428, 429, 430, 431, 432, 433, 434, 435, 436, 437, 438, 439, 440, 441, 442, 443, 444, 445, 446, 447, 448, 449, 450, 451, 452, 453, 454, 455, 456, 457, 458, 459, 460, 461, 462, 463, 464, 465, 466, 467, 468, 469, 470, 471, 472, 473, 474, 475, 476, 477, 478, 479, 480, 481, 482, 483, 484, 485, 486, 487, 488, 489, 490, 491, 492, 493, 494, 495, 496, 497, 498, 499, 500, 501, 502, 503, 504, 505, 506, 507, 508, 509, 510, 511, 512, 513, 514, 515, 516, 517, 518, 519, 520, 521, 522, 523, 524, 525, 526, 527, 528, 529, 530, 531, 532, 533, 534, 535, 536, 537, 538, 539, 540, 541, 542, 543, 544, 545, 546, 547, 548, 549, 550, 551, 552, 553, 554, 555, 556, 557, 558, 559, 560, 561, 562, 563, 564, 565, 566, 567, 568, 569, 570, 571, 572, 573, 574, 575, 576, 577, 578, 579, 580, 581, 582, 583, 584, 585, 586, 587, 588, 589, 590, 591, 592, 593, 594, 595, 596, 597, 598, 599, 600, 601, 602, 603, 604, 605, 606, 607, 608, 609, 610, 611, 612, 613, 614, 615, 616, 617, 618, 619, 620, 621, 622, 623, 624, 625, 626, 627, 628, 629, 630, 631, 632, 633, 634, 635, 636, 637, 638, 639, 640, 641, 642, 643, 644, 645, 646, 647, 648, 649, 650, 651, 652, 653, 654, 655, 656, 657, 658, 659, 660, 661, 662, 663, 664, 665, 666, 667, 668, 669, 670, 671, 672, 673, 674, 675, 676, 677, 678, 679, 680, 681, 682, 683, 684, 685, 686, 687, 688, 689, 690, 691, 692, 693, 694, 695, 696, 697, 698, 699, 700, 701, 702, 703, 704, 705, 706, 707, 708, 709, 710, 711, 712, 713, 714, 715, 716, 717, 718, 719, 720, 721, 722, 723, 724, 725, 726, 727, 728, 729, 730, 731, 732, 733, 734, 735, 736, 737, 738, 739, 740, 741, 742, 743, 744, 745, 746, 747, 748, 749, 750, 751, 752, 753, 754, 755, 756, 757, 758, 759, 760, 761, 762, 763, 764, 765, 766, 767, 768, 769, 770, 771, 772, 773, 774, 775, 776, 777, 778, 779, 780, 781, 782, 783, 784, 785, 786, 787, 788, 789, 790, 791, 792, 793, 794, 795, 796, 797, 798, 799, 800, 801, 802, 803, 804, 805, 806, 807, 808, 809, 810, 811, 812, 813, 814, 815, 816, 817, 818, 819, 820, 821, 822, 823, 824, 825, 826, 827, 828, 829, 830, 831, 832, 833, 834, 835, 836, 837, 838, 839, 840, 841, 842, 843, 844, 845, 846, 847, 848, 849, 850, 851, 852, 853, 854, 855, 856, 857, 858, 859, 860, 861, 862, 863, 864, 865, 866, 867, 868, 869, 870, 871, 872, 873, 874, 875, 876, 877, 878, 879, 880, 881, 882, 883, 884, 885, 886, 887, 888, 889, 890, 891, 892, 893, 894, 895, 896, 897, 898, 899, 900, 901, 902, 903, 904, 905, 906, 907, 908, 909, 910, 911, 912, 913, 914, 915, 916, 917, 918, 919, 920, 921, 922, 923, 924, 925, 926, 927, 928, 929, 930, 931, 932, 933, 934, 935, 936, 937, 938, 939, 940, 941, 942, 943, 944, 945, 946, 947, 948, 949, 950, 951, 952, 953, 954, 955, 956, 957, 958, 959, 960, 961, 962, 963, 964, 965, 966, 967, 968, 969, 970, 971, 972, 973, 974, 975, 976, 977, 978, 979, 980, 981, 982, 983, 984, 985, 986, 987, 988, 989, 990, 991, 992, 993, 994, 995, 996, 997, 998, 999, 1000).

"It happens not infrequently," he says, "that at the first time of making water, some blood comes along with it. This is rather favorable, as when the stricture is destroyed, the stricture usually proves to be less than expected, that at the next time the stricture passes through it. Every other day appears to be possible to be applied to it in order to apply the caustic. I have, however, done it every day, or very occasionally, when the stricture was not healed, without any detriment."—(H. Chas. p. 275, 276, 277, 278, 279, 280, 281, 282, 283, 284, 285, 286, 287, 288, 289, 290, 291, 292, 293, 294, 295, 296, 297, 298, 299, 300, 301, 302, 303, 304, 305, 306, 307, 308, 309, 310, 311, 312, 313, 314, 315, 316, 317, 318, 319, 320, 321, 322, 323, 324, 325, 326, 327, 328, 329, 330, 331, 332, 333, 334, 335, 336, 337, 338, 339, 340, 341, 342, 343, 344, 345, 346, 347, 348, 349, 350, 351, 352, 353, 354, 355, 356, 357, 358, 359, 360, 361, 362, 363, 364, 365, 366, 367, 368, 369, 370, 371, 372, 373, 374, 375, 376, 377, 378, 379, 380, 381, 382, 383, 384, 385, 386, 387, 388, 389, 390, 391, 392, 393, 394, 395, 396, 397, 398, 399, 400, 401, 402, 403, 404, 405, 406, 407, 408, 409, 410, 411, 412, 413, 414, 415, 416, 417, 418, 419, 420, 421, 422, 423, 424, 425, 426, 427, 428, 429, 430, 431, 432, 433, 434, 435, 436, 437, 438, 439, 440, 441, 442, 443, 444, 445, 446, 447, 448, 449, 450, 451, 452, 453, 454, 455, 456, 457, 458, 459, 460, 461, 462, 463, 464, 465, 466, 467, 468, 469, 470, 471, 472, 473, 474, 475, 476, 477, 478, 479, 480, 481, 482, 483, 484, 485, 486, 487, 488, 489, 490, 491, 492, 493, 494, 495, 496, 497, 498, 499, 500, 501, 502, 503, 504, 505, 506, 507, 508, 509, 510, 511, 512, 513, 514, 515, 516, 517, 518, 519, 520, 521, 522, 523, 524, 525, 526, 527, 528, 529, 530, 531, 532, 533, 534, 535, 536, 537, 538, 539, 540, 541, 542, 543, 544, 545, 546, 547, 548, 549, 550, 551, 552, 553, 554, 555, 556, 557, 558, 559, 560, 561, 562, 563, 564, 565, 566, 567, 568, 569, 570, 571, 572, 573, 574, 575, 576, 577, 578, 579, 580, 581, 582, 583, 584, 585, 586, 587, 588, 589, 590, 591, 592, 593, 594, 595, 596, 597, 598, 599, 600, 601, 602, 603, 604, 605, 606, 607, 608, 609, 610, 611, 612, 613, 614, 615, 616, 617, 618, 619, 620, 621, 622, 623, 624, 625, 626, 627, 628, 629, 630, 631, 632, 633, 634, 635, 636, 637, 638, 639, 640, 641, 642, 643, 644, 645, 646, 647, 648, 649, 650, 651, 652, 653, 654, 655, 656, 657, 658, 659, 660, 661, 662, 663, 664, 665, 666, 667, 668, 669, 670, 671, 672, 673, 674, 675, 676, 677, 678, 679, 680, 681, 682, 683, 684, 685, 686, 687, 688, 689, 690, 691, 692, 693, 694, 695, 696, 697, 698, 699, 700, 701, 702, 703, 704, 705, 706, 707, 708, 709, 710, 711, 712, 713, 714, 715, 716, 717, 718, 719, 720, 721, 722, 723, 724, 725, 726, 727, 728, 729, 730, 731, 732, 733, 734, 735, 736, 737, 738, 739, 740, 741, 742, 743, 744, 745, 746, 747, 748, 749, 750, 751, 752, 753, 754, 755, 756, 757, 758, 759, 760, 761, 762, 763, 764, 765, 766, 767, 768, 769, 770, 771, 772, 773, 774, 775, 776, 777, 778, 779, 780, 781, 782, 783, 784, 785, 786, 787, 788, 789, 790, 791, 792, 793, 794, 795, 796, 797, 798, 799, 800, 801, 802, 803, 804, 805, 806, 807, 808, 809, 810, 811, 812, 813, 814, 815, 816, 817, 818, 819, 820, 821, 822, 823, 824, 825, 826, 827, 828, 829, 830, 831, 832, 833, 834, 835, 836, 837, 838, 839, 840, 841, 842, 843, 844, 845, 846, 847, 848, 849, 850, 851, 852, 853, 854, 855, 856, 857, 858, 859, 860, 861, 862, 863, 864, 865, 866, 867, 868, 869, 870, 871, 872, 873, 874, 875, 876, 877, 878, 879, 880, 881, 882, 883, 884, 885, 886, 887, 888, 889, 890, 891, 892, 893, 894, 895, 896, 897, 898, 899, 900, 901, 902, 903, 904, 905, 906, 907, 908, 909, 910, 911, 912, 913, 914, 915, 916, 917, 918, 919, 920, 921, 922, 923, 924, 925, 926, 927, 928, 9

and, p. 26). However, supposing that the foregoing statement refers to operations for stones, and that the average number of operations for the preparation of Great Britain and Ireland is annually about one for each 100,000 inhabitants, the inference drawn by Dr. Marten, which also does not agree with other official reports, cannot be accepted, because, in the total number of children operated on having been admitted into the stone hospitals, even when every admission is made for the stone completed in the calculation, the proportion of operations is far beyond the average, with reference to the population in general. And this difference is most noticeable in the children of the poor than in those of the higher classes, it is a fact which nevertheless is explained by the fact that the stone is more of the population of the poor and laboring classes.

In the period of life between the age of thirty and twenty, and that of forty, the liability to stone in the bladder is much less than in infancy, childhood, or old age. And, in point, many of the cases which so present themselves in adults or middle-aged individuals, passed beyond an earlier period of life or are owing to some extraneous cause.

According to Rogers, in old men who are particularly subject to calculi, the disposition to the stone of the prostate always commences during life; and, being at these seasons in frequent—*British Med. Jour.* 1852, p. 295, &c.

The following table, collected by Dr. French, exhibits the proportion of stone, death before and after surgery, and of their occurrence in the different parts.

	British	French	German	Total	Consisting of	
14 years and under, Above 14 years.	128 127	90 149	225 171	543 347		
	303	239	396		1114	44

Thus, nearly one-half of the whole number of stone cases occur before the completion of the 14th year; and it appears also from Mr. Smith's valuable reports, that there is an enormous increase in the number of cases about the age of 16th years.—(*See Practice of Surgery*, p. 218; and *N. Smith*, in *Med. Chron. Trans.* vol. 1.)

Dr. Marten has collected the comparative frequency of the stone in various countries, and in the different seasons of life, and tried to ascertain, so far as frequency be influenced by varieties of climate, or season, as by prevalence in our islands and elsewhere. He reported, regarding all the great hospitals of the metropolis, in the hope of getting at some general

records concerning the vast number of patients, in whom lithotomy had been performed in stone calculi. In London, it proved impossible to obtain all the particulars of such cases, in so many of them had been preserved. The Norwich Hospital, however, afforded him some data which are interesting. All the cases which have been retained in that hospital for 44 years, viz. from 1772 to 1816, and which amount to 536, have been carefully preserved, with the circumstances connected to each stone, and the result of the operation according to records. Dr. Marten has given the result of these records in the following table.

Male Patients.	Number of Operations.			Deaths.		
	Children under 14.	Adults.	Total.	Children.	Adults.	Total.
	27 0	261 20	278 20	12 1	25 1	37 2
	27	281	308	13	26	39

It appears, says Dr. Marten, from the above table, that the stone almost invariably is stone of lithotomy in the Norwich Hospital during 44 years, has been 17, or 27 in every two years; and that the total number of total cases in the 536 operations, is 76, or 1 in 7, or 4 in 29. The proportion of deaths in children during the 20 years that lithotomy attended operations for stone there was very poor. In the British lithotomy, the risk in children seems to have been about equal to what it has been in adults. In all calculations of this kind, however, it is to be recollected, that in operations for stone many are done not only by surgeons of various degrees of skill, but in different ways, and even with instruments and great diversity such operations do not give the fair average of any one method of operation.

According to Mr. Smith, the mortality from lithotomy in the British Hospital, has been in the following proportion:

Age.	Kind of Mortality.
10 years and under (1840)	1 in 45
Between 10 and 20	1 in 5
20—30	1 in 5
30—40	1 in 5
40—50	1 in 5
50—60	1 in 5
60—70	1 in 5
70—80	1 in 5
Mean of all ages.	1 in 41

From 1762 to 1772	From 1772 to 1782	From 1782 to 1792	From 1792 to 1802	From 1802 to 1812
1762	1772	1782	1792	1802
1772	1782	1792	1802	1812
1782	1792	1802	1812	1822
1792	1802	1812	1822	1832
1802	1812	1822	1832	1842

Mean of all ages, 1 in 7.43

The preceding table is also from Mr. Smith's paper, and refers to the Dorset Hospital.—*See Med. Chron.* 1840 vol. 16.

In the Norwich Infirmary, the mortality has been much less in children than adults. But in St. Bartholomew's, the proportion of death in children during the 20 years that lithotomy attended operations for stone there was very poor. In the British lithotomy, the risk in children seems to have been about equal to what it has been in adults. In all calculations of this kind, however, it is to be recollected, that in operations for stone many are done not only by surgeons of various degrees of skill, but in different ways, and even with instruments and great diversity such operations do not give the fair average of any one method of operation.

Next, where the patients are equally intractable, but the results of surgical treatment of operations on them are completely different, the skill of the surgeon, the particular methods of operation pursued, the kind of instruments used, the general condition of the hospital itself, and the constitution after the patients are put to bed, are considerations by which questions of difficulty in lithotomy must be judged.

From the year 1772 to 1816, the Norwich Hospital received 62,500 patients of all kinds, making an average of 425 annual admissions; and Dr. Marten observes, that the proportion of 1000 patients of lithotomy out of 48,000 patients, which corresponds to about 1 in 38, exceeds as an alarming degree, that obtained from any of the other public hospitals, where records be collected.

Next to the records of the Norwich Hospital, Dr. Marten derived the most valuable information of the

kind from Chelmsford, took notice in his work on anatomy, that during the course of his public practice in St. Thomas's Hospital, a period of about 30 years, he had performed the operation of the stone 212 times, and was only 20 patients. This was when 2 came to 22, which is much less than the contemporary average.

In St. Thomas's Hospital, during 10 years, the operation of lithotomy had been done on an average 41 times in each year; and one case of stone had been cured in each 325 patients admitted.

In St. Bartholomew's, lithotomy was performed 56 times in the years 1812, 1813, 1814, 1815, and 1816. The average was about 11, or 1 in each 340 patients of 33 discharges.

In St. George's Hospital, lithotomy had been performed on an average about 3 to 40 times annually, during the space of 21 or 30 years. The proportion of calculus patients then was also estimated by Dr. Martin as 1 in about 300 cases for all kinds.

Dr. Martin's inquiries induced him to think, not, on the whole, lithotomy in the London hospitals the same part had been probably becoming less frequent; and still, nevertheless, they are owing partly to a real increase in the frequency of the stone, from some alteration in the habits of the people; partly to the use of aqueous medicines; and partly to the circumstance of calculus patients not residing so exclusively as you formerly did close to the great London hospitals for the operation.

In the Royal Infirmary at Edinburgh the average number of stone cases annually, during the six years preceding the period of Dr. Martin's publications, is said to have exceeded 5, although about 550 patients had been admitted there every year.

Dr. Martin was satisfied by M. Rivet, surgeon in La Charité at Paris, on 6 or 7 days, says of stone occur every year out of about 2000 patients; and that the proportion of stone cases the operation there is 1 in 5 to 6.

With respect to the Hospital for Blind Men, in the same city, Dr. Martin states, on the authority of Dr. Hunt, that although cases of stone are received every year only that establishment, where about 2000 children of both sexes are regularly admitted. There have been only 3 cases in 10 years, and, which is remarkable, only 2 deaths from the operation in the course of the last seven years.

Dr. Martin has been surprised that lithotomy is comparatively rare in Vienna; not on account of the want of good surgeons, or the infrequency occurrence of stone cases in that part of the continent, but in consequence of the little attention paid to this disease by the medical corporations of the Austrian Empire.

At Geneva, says Dr. Martin, in a population of 20,000, lithotomy has been performed only thirteen times in the last twenty years, though good surgeons are never wanting in that town to perform the operation whenever an opportunity presents itself. Out of these thirteen patients, seven were not strictly Genevese, though belonging to the neighbouring districts, and one was an Englishman; so that the disease would, at first sight, appear to be more frequent at Geneva. But, continues Dr. Martin, if the mortality of the Genevese population be taken into account, this proportion of calculus cases may not yet very short of that observed in other places. At Lyons a population more than twice as large being drawn from Geneva, the disease is stated to be rather frequent.

With regard to the chemical nature of urinary calculi, there is not much known until 1795, when Berzelius published on the subject in the *Frankische Transactions*. He there stated, that all the urinary calculi which he had examined consisted of a peculiar concrete substance, now well known by the name of hippuric or uric acid, which he also showed was soluble in alkaline liquids. Berzelius further discovered that the uric matter was in some degree capable of being dissolved in cold water; that this solution possessed acid properties, and in particular that of reddening litmus; and it was added upon this peculiar manner when heated in strong acid, and finally that lemon juice contains contained "the substance in question, or less exactly, and in few but it appears to be one form of a body coloured redness by the most effect is evident.

The discovery made by Berzelius was confirmed by Berghman and Marsson, and the decomposition of the subject was afterwards pursued by others with re-

sulting order. As Professor Murray observes, these views continued to be expanded and extended in these calculations and on their contents. At length was fully ascertained that their nature and effects, which were composed of one acid, and finally, our knowledge of them has been chiefly attributed by the researches of Proust, Wollaston, Fourcroy, and Berzelius. Several important facts have also been discovered by the talents and industry of some distinguished men, viz. Dr. Wray, in Manchester, Professor Brandt, of the Royal Institution of London, Dr. Martin, late of Guy's Hospital, and Dr. Ferriaroli, of London. The facts and considerations of the same matter render it probable, however, that the nature and origin of pure uric acid being explained to the mind is necessarily correct; but that this acid "is better said to exist in a state of combination with ammonia, and that in reality this fluid contains no ammonia, and at all,"—(*On the Nature, &c. of Urinary Calculi*, c. 21.)

The credit which is due to Dr. Wollaston for his valuable and original discoveries respecting uric acid is very considerable; a truth, which I have particularly pleasure in recording here, since his merits have not been fully appreciated by the French writers. Indeed, as Dr. Martin observes, it is the more desirable that his claims should be placed in the most point of view by the late celebrated Dr. Ferriaroli, who, in his "Synthèse des Composés Chimiques," and in his various papers on this point in *Comptes Rendus*, is a most unimpeachable authority on this subject. Indeed, and in describing some matter nearly as to those previously recorded and published by the English chemists, has placed them in his credit. Yet Dr. Wollaston's paper was printed in our *Philosophical Transactions* ten years before Ferriaroli published his Memoire in the *Annuaire de Chimie*; and three years before he gave to the world his "Mémoire des Composés Chimiques," and is contained in these works a paper of Dr. Ferriaroli on the same subject, published in a volume of the *Philosophical Transactions* (No. 1799) subsequent to that which contained the account of Dr. Wollaston's discovery.—(*See Memoire d'Analyse Chimique*, &c. &c. *Also Murray's Dispensary of Chem.* vol. 1, p. 20, 1817, p. 200.)

It would appear, then, that Berzelius had shown the nature of those urinary calculi which consist of uric acid, but that Dr. Wollaston first ascertained the nature of several other kinds, some of which have been described at a later period by Ferriaroli and Berzelius. On the whole, there are the results of my inquiries, whose chemical properties were explained by Dr. Wollaston, and no less than five kinds of the urinary system. These are, 1st, *Calcium oxalate*, 2dly, *The uric acid*, 3dly, *The uric acid*, 4thly, *The uric acid*, 5thly, *The uric acid*, 6thly, *The uric acid*, 7thly, *The uric acid*, 8thly, *The uric acid*, however, to find poison, both marine and nitric acid dissolve it slowly. The solution of the alkaline carbonates decomposes, as Fouquier and Vauquelin have pointed out, and this affords the easiest method of analyzing it. The carbonate in powder being placed in the solution, effluvia of base is soon formed, which quickly insoluble, and is easily distinguished by the difference produced by the addition of weak acetic acid, which is obtained in passing the compound of carbonic acid with the alkali of the alkaline carbonate. From this the carbonic acid may be precipitated by the action of lead or of sulphur; and this solution, being formed, may be afterwards decomposed by over-boiling acid. Another method of analyzing this calculus is by exposure to heat; the acid is decomposed, and by raising the heat sufficiently, pure base is obtained, amounting to about a third of the weight of the calculus. According to Fouquier and Vauquelin, the nature of these carbonates consequently admits neither than any other. This general matter applied to them to be a solution of alkaline and acids. The composition of a calculus of this species, analyzed by Mr. Berzeli, was as follows of fixed air, 60 grains; nitric acid, 16 grains; phosphate of lime, 12 grains; animal matter, 4 grains.

1. The *Calcule Grosse Calcairee* is small, and very rare. It was first described by Dr. Williams—*Phil. Trans.* 1797, 524. In external appearance, it bears a greater resemblance to the triple phosphate of ammonia than any other sort of calculus. However, it is less opaque, and poor and coarse of internal texture, but appears as one mass, continuously crystallized throughout its substance. It has a pearly, semitransparent, and a pearly glassy lustre. Under the microscope, a great deal of irregularity is observed from that of lime, and, in the space of grains, and in consequence of the readiness with which this species of calculus unites both with acid and alkalies, in common with other bodies, and the fact of its also containing oxygen (as is proved by the formation of carbonic acid &c.) (Berzeli), Dr. Williams named it as such, and the term *calculus* was added from its having been slightly fused only in the bladder in two cases only. Dr. Hunter, however, has incorrectly not only on less than these instances of pure lime, but of calcareous, all of which were unquestionably of renal origin.

2. *Alteringing Calcaire*. This stone is frequently alternate with layers of calcareous lime or with the phosphate. Sometimes also the uriciferous alternate with the phosphatic, and is a few degrees, there is even four species of calculus occur in the same stone, disposed in distinct concentric layers. On the comparative frequency of these and other varieties of calculi, Dr. Ferri's work contains valuable information.

3. *Compacted Calcaire*, with *Med. Ferri* (Berzeli) rather rarely allied. Under this title, Dr. Ferri comprehends certain calculi which have no characteristic feature by which they can be considered as distinctly belonging to any of the other classes. He observes, that they are sometimes distinguished by their more or less irregular figure, and their less distinct crystalline texture; by their being less firmly, or at, at least, less easily, and by their often possessing a considerable hardness. By chemical analysis, combined results are obtained—*See Essay on the Chem. and Med. Hist. of Calcairee* (Berzeli, p. 30).

4. *Calcaire of the Prostate Gland*. The composition of these calculi is said to have been first analyzed by Dr. Williams—*Phil. Trans.* for 1797. They all consist of phosphate of lime, the earth being regarded as in base. Their size varies from that of a pin's head to that of a hazel-nut. Their figure does not depend on the gland, and they are of a yellowish colour.

Fouquier has described a species of urinary calculus, which is characterized by being composed of the uric or uric acid of ammonia. Dr. Williams, Mr. Berzeli, and Dr. Ferri, all find, however, sufficiently supports the presence of the uric acid in a large of the specimens which they examined. As they found that the triple phosphate, before which acid analysis, are frequently present in lime calculi, it is conjectured that these characteristics may have given rise to the analytical results, from which the existence of uric acid of ammonia has been inferred—*See Essay on Phil. Trans.* 1797, *Merret's Essay*, p. 12.

The recent investigations of Dr. Ferri, however, tend to establish the reality of the nature of ammoniacal calculi.

Dr. Ferri met with two varieties of uric acid, called uric acid, and uric acid, which differ in their external appearance. One of these, he supposes to be uric acid, uric acid, first described, yellowish, and of a most characteristic property is that of having a brown-colored compound, which would give to the acid. The chemical properties of the uric acid, called uric acid, described by Dr. Ferri, correspond to that of uric acid, and he therefore suggests the possibility of distinguishing it by the tests of uric acid. The uric acid described of these two substances, I have only in this position's body.

5. *Calcaire of Lime Calcaire*. This variety is not comprehended by Dr. Ferri, as, according to the composition of uric acid. But according to Mr. Berzeli, there can be no doubt of the fact. It is Dr. Ferri, of Calcaire, he says, detected in a variety of four specimens. A notice of it will be found in Mr. Berzeli's *Ann.* for 1807, vol. 40, p. 10. It is the result of a common calculus, given to me by Mr. G. H. Berzeli, of Calcaire, the calculus of which is a common cluster, and has a shell long, and one broad. The publication of that paper (continued in Mr. Berzeli's *Ann.* for 1807, vol. 40, p. 10), Mr. G. H. Berzeli, of Calcaire, sent me some small, shaped calculi, which he gathered from a small number of 15 men used in the previously noted by his works, which are entirely calcareous of lime, and he gathered by several means. (See *Ann. Chem. Phys.* vol. 11, p. 14). Dr. Ferri has also seen some small, shaped, almost entirely of uric acid of lime.

6. *Calcaire of Lime Calcaire*. This variety is not comprehended by Dr. Ferri, as, according to the composition of uric acid. But according to Mr. Berzeli, there can be no doubt of the fact. It is Dr. Ferri, of Calcaire, he says, detected in a variety of four specimens. A notice of it will be found in Mr. Berzeli's *Ann.* for 1807, vol. 40, p. 10. It is the result of a common calculus, given to me by Mr. G. H. Berzeli, of Calcaire, the calculus of which is a common cluster, and has a shell long, and one broad. The publication of that paper (continued in Mr. Berzeli's *Ann.* for 1807, vol. 40, p. 10), Mr. G. H. Berzeli, of Calcaire, sent me some small, shaped calculi, which he gathered from a small number of 15 men used in the previously noted by his works, which are entirely calcareous of lime, and he gathered by several means. (See *Ann. Chem. Phys.* vol. 11, p. 14). Dr. Ferri has also seen some small, shaped, almost entirely of uric acid of lime.

7. *Calcaire of Lime Calcaire*. This variety is not comprehended by Dr. Ferri, as, according to the composition of uric acid. But according to Mr. Berzeli, there can be no doubt of the fact. It is Dr. Ferri, of Calcaire, he says, detected in a variety of four specimens. A notice of it will be found in Mr. Berzeli's *Ann.* for 1807, vol. 40, p. 10. It is the result of a common calculus, given to me by Mr. G. H. Berzeli, of Calcaire, the calculus of which is a common cluster, and has a shell long, and one broad. The publication of that paper (continued in Mr. Berzeli's *Ann.* for 1807, vol. 40, p. 10), Mr. G. H. Berzeli, of Calcaire, sent me some small, shaped calculi, which he gathered from a small number of 15 men used in the previously noted by his works, which are entirely calcareous of lime, and he gathered by several means. (See *Ann. Chem. Phys.* vol. 11, p. 14). Dr. Ferri has also seen some small, shaped, almost entirely of uric acid of lime.

8. *Calcaire of Lime Calcaire*. This variety is not comprehended by Dr. Ferri, as, according to the composition of uric acid. But according to Mr. Berzeli, there can be no doubt of the fact. It is Dr. Ferri, of Calcaire, he says, detected in a variety of four specimens. A notice of it will be found in Mr. Berzeli's *Ann.* for 1807, vol. 40, p. 10. It is the result of a common calculus, given to me by Mr. G. H. Berzeli, of Calcaire, the calculus of which is a common cluster, and has a shell long, and one broad. The publication of that paper (continued in Mr. Berzeli's *Ann.* for 1807, vol. 40, p. 10), Mr. G. H. Berzeli, of Calcaire, sent me some small, shaped calculi, which he gathered from a small number of 15 men used in the previously noted by his works, which are entirely calcareous of lime, and he gathered by several means. (See *Ann. Chem. Phys.* vol. 11, p. 14). Dr. Ferri has also seen some small, shaped, almost entirely of uric acid of lime.

9. *Calcaire of Lime Calcaire*. This variety is not comprehended by Dr. Ferri, as, according to the composition of uric acid. But according to Mr. Berzeli, there can be no doubt of the fact. It is Dr. Ferri, of Calcaire, he says, detected in a variety of four specimens. A notice of it will be found in Mr. Berzeli's *Ann.* for 1807, vol. 40, p. 10. It is the result of a common calculus, given to me by Mr. G. H. Berzeli, of Calcaire, the calculus of which is a common cluster, and has a shell long, and one broad. The publication of that paper (continued in Mr. Berzeli's *Ann.* for 1807, vol. 40, p. 10), Mr. G. H. Berzeli, of Calcaire, sent me some small, shaped calculi, which he gathered from a small number of 15 men used in the previously noted by his works, which are entirely calcareous of lime, and he gathered by several means. (See *Ann. Chem. Phys.* vol. 11, p. 14). Dr. Ferri has also seen some small, shaped, almost entirely of uric acid of lime.

10. *Calcaire of Lime Calcaire*. This variety is not comprehended by Dr. Ferri, as, according to the composition of uric acid. But according to Mr. Berzeli, there can be no doubt of the fact. It is Dr. Ferri, of Calcaire, he says, detected in a variety of four specimens. A notice of it will be found in Mr. Berzeli's *Ann.* for 1807, vol. 40, p. 10. It is the result of a common calculus, given to me by Mr. G. H. Berzeli, of Calcaire, the calculus of which is a common cluster, and has a shell long, and one broad. The publication of that paper (continued in Mr. Berzeli's *Ann.* for 1807, vol. 40, p. 10), Mr. G. H. Berzeli, of Calcaire, sent me some small, shaped calculi, which he gathered from a small number of 15 men used in the previously noted by his works, which are entirely calcareous of lime, and he gathered by several means. (See *Ann. Chem. Phys.* vol. 11, p. 14). Dr. Ferri has also seen some small, shaped, almost entirely of uric acid of lime.

Mirreling calculi compared to human manure, and the like; but Dr. Frost offers good reasons for believing that the dark, brown, or even black, stones, should be deposited again. For additional illustration in this behalf of the subject, I refer now to Dr. Frost's valuable work.

The cause being a severe affliction, and the operation extremely hazardous and painful, a variety of experiments have been instituted for the purpose of discovering a means for urinary calculi. Altho, however, all the various diseases which have been tried, have been attended with very limited, and by no means successful, success, notwithstanding many persons may have been delivered into a curative solution.

The disposition of stones in the bladder has been ascribed by various physicians, as they are urged, and he daily injected into this vessel. At the present day, practitioners from their employers, very much to the confusion of these particulars, diuretics or acids of the constitution in which the formation of urinary calculi depend; and upon, certainly, seems to be placed in the mind, that it is not necessary for the dissolution of urinary concretions. It is certain that, in the latest period, many different opinions have been advanced; and among these, some of the most recent are, the great variety in the composition of calculi; the impossibility of knowing the exact ingredients of a stone while it is situated in the bladder; though some useful suggestions have been advanced by the judicious, as the point have been recently stated by Dr. Frost; and, thus, if the theory advanced were substantiated, as advanced upon chemical principles applied to urinary concretions can be the case, it is obvious that any practice taken by the present are liable to serious changes of the urinary canal, and to the muscular and vascular system, that it is not so hazardous, difficult to get over as an untried and untried effective remedy than the bladder, while, at the same time, it is the way of the bladder through a solution, the bladder itself must be incapable of holding the application, and the patient lose the life in the experiment.

As the Frost will observe, a calculus in the bladder may be considered a diseased phlegm in a solution of various principles, but contains quantity of water. If any of the more insoluble of these principles are in this solution in a state of supersaturation, the calculus will either a matter, reject which the stone will be deposited. But if more water is in a state of excess, or more water can be deposited, and the calculus will not increase in bulk.

When we analyze the chemical properties of the stone, says Dr. Maier, will have that "if any alkali (a few drops of ammonia for instance) be added to recent urine, a white cloud appears, and is followed, consisting of phosphate of lime with some strontian-magnesian phosphate, subsides in the proportion of about two grains of the phosphate from four ounces of urine. Lime-water produces a precipitate of a similar kind, which is still more copious; the lime, in combining with the excess of phosphate, and perhaps, also, of lactic acid, not only precipitates the phosphate of lime, which these acids hold in solution, but decomposes the other phosphate, thus producing an additional quantity of the phosphate of lime, which is deposited."

"If on the contrary (wherever the same alkali), a small quantity of any acid, either the phosphoric, the acetic, or, indeed, even common tartar, be added to recent urine, the white cloud, and the alkali be added to stand for one or two days, small white crystalline particles of uric acid will be gradually deposited on the transverse of the vessel."

"It is on these two points, then, that our principles of chemical treatment clearly rest. Whenever the lithic secretion predominates, the alkalies are the appropriate remedies; and the acids, particularly the tartaric, are the acids to be resorted to, when the calcareous or magnesian lithic prevail in the deposits."—(P. 147, 148.)

The alkalies taken into the stomach certainly reach the urinary passages through the medium of the circulation; and it is also generally supposed that the acids likewise do, though this circumstance is still a question. Unfortunately, the quantity of uric acid or uric acid which may enter with the urine is so small, that no impression is made upon either of the organs.

The experience of Dr. Maier, Dr. Frost, and others, has clearly ascertained that such medicines are often capable of checking the tendency to the formation of stones, and sometimes of dissolving a calculus depending upon the altered state of the system. Indeed, Dr. Maier expresses his decided opinion, that even supporting and an atom of alkali or acid ever reached the bladder, still it would not be unreasonable to expect that these remedies may collectively produce the desired success during the later stages of inflammation; in other words, by controlling any morbid cause of acid in the urinary canal; and in the effort, by checking a tendency to inflammation or otherwise damping down inflammation, which, in the subsequent processes of inflammation, may give rise to calculus affections.—(P. 153.)

While tartaric acid is prescribed, from 5 to 25 drops may be given two or three times a day, diluted with a sufficient quantity of water.

The best way of taking the alkali is by drinking Soda Water as a common beverage. It is asserted, however, on the authority of Mr. G. H. Egan that, when the bladder is morbidly with uric acid, even the alkali will do no good; they also have the effect of depleting the urine of its acid properties.

Dr. Maier, with every appearance of probability, refers to uric acid itself as a solvent power; and he does not even adopt Mr. Berch's opinion, that this acid alone and the urine, when patients drink, might be improved with it.

But it would be inquired, if we knew of no other medicine will dissolve a stone, and if we know of no other medicine will dissolve the bladder and checking the tendency of the calculus, as follows must still be necessary? Two attempts for operating in the case of concretions may particularly come of the system and the urinary tract, to facilitate the removal of a calculus depends on two points; for it is true, that though uric acid may be quite incapable of dissolving a calculus, they return again one of the most and last of all, apparently the effect of the diuretic itself, as will be generally noticed, and sometimes afford such, that the operation may be postponed until the health is improved, or, if a very old subject, even be postponed until altogether. The aim is not of high importance, with the view of preventing relapse.

As the lithic acid calculus seems to be composed in the production of about two-thirds of the whole number of the urinary calculi, the removal of it has been a chief aim among modern practitioners. For this purpose, Maier, whose experiments tend to prove, that the lithic acid calculus may be induced and removed by alkalies from animal food, and other substances showing its nature, holds his position very much upon this alleged fact. His indications, however, are five in number, viz. 1. To know the quantity of uric acid produced by the kidneys; 2. To ascertain the quantity of uric acid, which is excreted; a statement which obviously is required, considering the quantity of uric acid in the urine, independently of the statement of Dr. Wilson Phillips, that the precipitating acid of such is the cause is formed off by the skin, and consequently that causing a deep performance of the cutaneous functions must, by these values, be required.—(See Medical Treatise, of the College of Physicians, vol. 5, 2. To prevent the lithic acid from increasing would form by increasing it. 4. When gravel and calculi are formed, to promote their discharge and attempt their dissolution.—(Archives, &c. see the Gravel, p. 42.)

For correcting the lithic acid diathesis, Dr. Frost generally, advises the avoidance of acids in diet, exercise, &c. Altho, as a quantity of acid is deemed more than the error of quality. Patients, he says, should abstain altogether from things which naturally dispose with them, and which are to be avoided (see p. 42); such as heavy unrefined bread, food boiled and fat puddings, salad and green herbs, sweet fruits, and of the digestive organs be subjected to any of every kind. It is found also, that, and ultimately those of an aqueous quality should be avoided. The removal of fatness, the preserving a regular state of the bowels, and the removal of all of offensive conditions are likewise considered.—(Frost, on Gravel, &c. p. 153.)

According to this same author, the treatment of lithic

as I have mentioned in the article *Prostatic Gland*, Disease of, Mr. Wilson has succeeded in constructing elastic catheters which may be retained more than a fortnight in the urethra without becoming obstructed, besides obviating the advantage of always retaining a catheter.

1. *Of the Retention of Urine, in adult persons of advanced age and sex.*—This disorder is not common in elderly persons, but it is generally observed to be one of the gravest to which their period of life is particularly exposed. In these the bladder is less irritable than in younger subjects, and hence it is not so soon irritated by the pressure of the urine. In fact, it is sometimes a painful swelling arises from the distention of the contents of the bladder, and the patient is aware of the necessity to discharge themselves. The bladder then contracts, but still would not be able to expel its contents, were it not for the powerful action of the abdominal muscles. Now is the expulsion of the urine even less complete; since the bladder no longer retains the power of expelling the volume of its contents. On the contrary, after each expiration, some urine is still left, undischarged, and always constitutes an important secretion. The quantity daily excreted, and at length it may take half the fluid secreted in the bladder is voided in each expiration.

The muscular particularly attacks old subjects of a plethoric staid body, and of sedentary and cold habits. It also especially afflicts those who, from carelessness or indolence, do not take the exercise to expel the last drops of urine; and others who are accustomed to discharge their urine into a pot, as they lie in bed, instead of using the urinal.

In these cases, the urethra and neighbouring parts seem to be free from every species of inflammation; the cause of the urine, which has always come away freely and in a full stream, although it could not be discharged with the same force, not to the same distance as formerly. At length, instead of discharging as much as it flows out, it falls down perpendicularly behind the legs. Towards the close of the expiration, the patient is also not sensible of the final expulsive effort of the bladder, or which he used to be conscious in his younger days. When he is about to make water, he is obliged to wait some time before the emission commences; and as the disorder increases, he cannot make water without considerable effort; the quantity of urine voided with time manifestly decreases; the desire to empty the bladder becomes more and more frequent; and lastly, the urine is expelled away by drops, and in successive small quantities.

In this state, the patient's sufferings are not very great. The trouble caused by the bladder above the neck is trifling, and if it be proved upon with some force, a certain quantity of urine is discharged from the urethra.

The retention of urine arising from old age is tedious, complete, and arises after having filed and distended the bladder, discharging out of the urethra, so that the patient feels as much of this fluid as a pleuritic as he does in a state of health. Now is this species of retention to be constantly attended with very severe symptoms. It is not, as we saw, like complete retention, a suppression of the urinary secretion in the kidneys; and as the urine escapes through the urethra, after the bladder is distended to a certain degree, the disorder is less apt to produce a rupture of this organ, and therefore extraordinary of the urine. The swelling of the bladder this continuing, without any particular relief, except a sense of weight and the patient's distress. These circumstances have often led to serious mistakes; and the disorder has been all along at all times of day.

The sufferings are to continue the urine still rises the neck of the bladder. What the retention is, is judged, the proper action of the bladder will sometimes occur, after cold expels it, or it may be the hypostatic result of life, and the patient goes from a warm into a cold place to make water.

The patient will also be much careful to make water, frequently the last inclination he is to sit. At it this patient is to reflect that the bladder is more and more empty, the desire to make water increases; and the retention, which is last considered of only a few drops, very soon becomes complete. It is then that he is told, as Dr. Williams says, to try the expedient above recommended. No stimulus will now make the blad-

der contract sufficiently to expel the whole of its contents, and the catheter is the only thing by which this business is discharged. This artificial method is necessary, however, only after a temporary retention; for, as the bladder is more irritable in these, a catheter would be necessary if the symptoms of the disorder were but common. Hence, this suffering must either be left to the bladder or introduced as often as the patient has occasion to make water. When a skilled surgeon is constantly at hand, or when the patient knows how to put to relieve himself, Dr. Williams thinks it better to introduce the instrument only when the bladder is to be emptied, by which means the inconvenience arising from the continual presence of a foreign body will be avoided. In this case, either a silver catheter or a single gut per day is used with equal advantage; being the instrument to be kept in the bladder, one mode of retention, and provided with a curved end is to be preferred. As in old subjects the urethra is thick, a large catheter is generally found to enter more easily than one of smaller diameter.

As the treatment must be continued for some time, and should be as simple as possible, it is to be used, the patient should be instructed how to manage the catheter himself, and so it is just if he were to urinate in cold water. After a certain time, however, as long as it be not easy, the bladder must be introduced. When he finds that he can expel the urine, he should remove himself, because of the action, that the last drops of urine still are not voided, should they not be so, he must continue in the use of the instrument.

In this way of retention of urine, it has been proposed to draw into the bladder a certain quantity of Demulcent, but; but he does not give a formula of the medicine.

Warm fomentations, diuretic medicines, and leeches, and blisters, containing the urinary secretion, have been used, but, according to Wilson, these means frequently prove harmful to persons of advanced years, and are seldom useful. He mentions his own practice as the use of the catheter, and, when actually employed, often required the use of the bladder, and, when it failed, other means were used to effect. A blister over the perineum directed that.

Thinking over the cause of retention of urine, which by Dr. Williams is the effects of intemperance with meat, and the consequent use of diuretic drinks, and which considerably resembles, in their nature and manner, the retention from the weakened state of the bladder in elderly persons; I proposed to describe a mode of the disorder, will seem interesting in the practical purpose.

2. *Retention of Urine from an affection of the Neck of the Bladder.*—These cases are to be treated either in their origin, or in the course of their duration. Injuries of the brain are seldom followed by a retention of urine; but the complaint when attended with those of the spinal marrow. A compression of this medullary substance, by a tumor or fall upon the vertebral column; the injury which it causes in the lower and dislocations of the vertebrae or head's violent strain of the back; its compression by blood, or other matter, or other fluid effused in the spinal canal, and the effects which a variety of the same can have it; may all operate as so many causes of retention of urine. This form of the retention may be the consequence of tumours situated in the neck of the bladder, which are distinguished by the bladder. Whether the retention of urine, caused in these cases, arises from an affection of the nerves in the bladder, or from the general directly extending and the disordered powers, have been questioned, but the opinion of patients is in favor of the disorder arising from the neck of the bladder's affection.

When a retention of urine arises from injury to the neck of the bladder, the symptoms are, in general, more of the local character, as inflammation, and the symptoms of the general system are less extensive. The patient suffers very little of these are important of these conditions, and it is not complained of anything being wrong in the function of the urinary system. The surgeon, aware that a retention of urine is common in these cases, should pause whether there is any inflammation of the prostate, whether by feeling the state of the prostate, or above the pubes, or by introducing a catheter.

As this species of retention of urine is one of a special

[illegible]

The inflammation is diffused in the inner tunic which may be regarded as the inner of the six outer membranes and thence as of the same, policy, together perhaps with the *chorion*.—See *Dislocations and Fractures of the Eye-balls*.—Further, *Membrane of*. In wounds and perforations of the eyeball, however, death has a high proportion of the blood resulting from exposure. This was done so, or near the point of the bone, which had been struck, and the spread of inflammation was proportioned to the strength of the patient. The patient was sometimes repeated the same day, and sometimes days in succession, and when the patient could not get the use of even blood, dry cupping was employed, while, in some cases, it would be argued less advantage than allowing the contents to escape. In diseases of the eye, Dr. Smith also preferred the name of cancer, more.

3. *Melospiza cinerea* from the collection of the British Museum thought that this form of the sparrow might very probably be called *cinerea*, because it is irreducibly produced by a primary mutation. Of course its breeding habits are all those of *cinerea*, which may bring in the other features of the constant, but its intermediate cases depend on whether upon the weakness and loss of its ability in the blacker, accompanied by the lapidary definition of its color. The disorder frequently occurs in persons, who from habitations, influence, or idiosyncrasy, neglect in some degree what they call their coloring, or who choose to give energy to the blacker in consequence of some temporary disturbance to the system. Although the appearance of 1876 the escape of the same no longer exists, and the blacker is in other respects sound, yet as this organ has been weakened by the previous disturbance of its work, it cannot now contract sufficiently to reproduce the whole of its color, and sometimes the loss of color.

The distinction is simple. For those at the bottom, as in other moments of crisis, another dialogue is to be sought. The outcome, when left to the Market, generally proves adverse to the improvement of the fate of this status. It is not inconceivable, however, that Jewish people will share any confidence in their direction, which were expressed by Deutscher, though they may join him in the approval of a more plain structure in general. When the crisis between the collector is, in itself, strong, and is perceived to arise in distress, and when it also passes far, between the collector and the system, it is a sign that the Market has regained its power of attraction, just like it usually itself makes the end of the last system. In that circumstance, the collector is to be discarded, and the next may gradually assume his usual mode of life. Thus when the crisis is completed only this first phase, the Collector cannot be said again, whereas the Market becomes different again, establishing a higher degree of peace in new order restored.

[illegible]

Twenty feet below, Salsbery affixed a 15-kilohertz transducer, the calliper being used only as the makeshift.

When there are 4 or 5 flies in a group, with 1 larva and 3 or 4 eggs, 3 or 4 may undergo larval development, but the rest of the cluster is lost for ever. In this intermediate case, the pattern may resemble the fertile case — much as it should be made to resemble, because it is, in fact, an intermediate case — (see Fig. 3) and (see O'Connor, 1963).

Among the local discoveries of this, when the coal fields proper of the hidden domain meet with the rest of the cathode, I have to mention the lignite, the anthracite, the bit, the sulphate of iron, the medicinal, the iron applied to the various, and kept open with the various element; and gold wastes in the typographic region.

In all cases where the integrity of the bladder is to be restored, whether from rupture, or paralytic, or the cause of retention, and where, though the bladder were again distended, a certain quantity of urine is retained daily, retention is a necessary result to be avoided. Thus, besides the chance of the disease being mistaken for an abscess, which, as I have stated, cannot be avoided in any case, urinary efflux may take place. Scattered were mentioned about a lady who had been advised to repair to some distant inland waters, with a view of supporting a tumor, which appeared after a difficult labor, and was supposed to be in the uterus itself. However, the growth turned out to be merely a retention of urine, as it disappeared as soon as the catheter was introduced. Here no suspicion had been entertained of the possibility of the cure, because the patient had voided her urine without any apparent difficulty, and in reasonable quantity, for the five or six weeks during which the swelling existed.

In a third, or Minority, case is recorded in which the swelling of the bladder was so considerable, that it was dangerous for driving. The absorption of a defective osseous layer, in calage without any particular pain, and the cause was at first supposed to be pregnancy. The lady, however, was reassured by the obstetrical attending her rapidly, attended with a great deal of discomfort of the lower extremities, arms, and face. The patient was then considered to be disengaged, and a suppository was sent her to stop the supplication. The evacuation of the belly was quite easy. Fortunately, before the operation was done, a kind of diastolic mucus was determined upon, and while this was being taken, the patient was attended with a total cessation of urine for three days; a suppuration which she had not previously suffered. It was now judged prudent to push a catheter before the breast was employed. Eighteen pints of urine were drawn off and the swelling of the abdomen subsided. The next day twelve more pints of urine were drawn off. The osseous, which was entirely seropunctate, disappeared. The application of cold water reestablished the tone of the bladder, so that when three pints of urine had been drawn off by means of the catheter, the patient herself could spontaneously expel three or four others, with the aid of pressure on the hypogastric area.

The inhibition of urine caused by weakness or paralysis of the bladder, and the swelling about the pubes, may continue a long while without any inconvenience. It being a sort of reflux along the sympathetic region, and frequent irritations make water. Nausea has been known to follow under the complaint more than six months.

4. *Retention of Urine from Information of the Bladder*.—According to Hager, writers have noticed different effects on information of the neck of the bladder, and in the case of a lesion of the body of this vessel. They have in fact advanced the first case as a cause of retention; and the last as a cause of nocturnal emissions. As a remark, briefly remarks Whistler, instead of being mentioned, has been expressed to denote an intrusion of urine, and is contrast with greater vigour. But if there had not been emissions at night, which could be referred to nothing but inflammation of the bladder, still another effect here, like retention; nor an inflamed muscle—these facts appeared to coincide, and if it be compared to it, its nature is almost fixed.

Further, larvae of this species are said to be particularly active in the species of vegetation. It is also frequently attracted by the smell of urine, or other effluvia. Larvae, feeding on the feces of the animal, or the excrement of the human, are common. This species of the

the cause of the retention of urine is easily removed, and the tone of the bladder is not impaired, then the remedy is not always necessary; as when the complaint is induced by a spasm or contraction of kind in the urethra. In other cases, as in which the cause is the difficulty of making water caused by a morbidly elevated, as in cases of leucorrhoea, the catheter must be employed. In stricture and various diseases of the bladder, this instrument is the only means of relieving the retention of urine, as nature will not do this by the removal of the cause. It is again to be known, however, that as there are various causes, so different measures are necessary to a removal of urine, as consequence of retention taking place between the upper portion of the urethra and the lower part of the bladder.

3. *Retention of Urine from Pressure of the Bladder upon the Vessels of the Bladder.*—Abnormalities in the structure of this lamina; between the internal and external urethra; and the morbidly contracted state of the prostate, may lead to a retention of the urine by pressure on the neck of the bladder. The lamina itself, existing in these cases, may tend to produce the obstruction by falling a spontaneous contraction of the superior part of the urethra. Here the relief of the retention of urine is to be effected by removing or relaxing the other abnormal which produces the retention. If this cannot be immediately accomplished, the catheter must be used, though, in several instances, it will be better to avoid even the mistake of the catheter, and try the effect of heating the warm bath, and warm, which will frequently enable the patient to make water. The hot water, however, will not suffice, when the cause of the retention is likely to continue a long time.

4. *Retention of Urine from Foreign Matter in the Bladder.*—Without intending to trespass the extensive kind of matter produced by cancerous, syphilitic diseases, and lymph in the bladder, those pass up to the case in which the stone is obstructed by a calculus of the neck of the bladder. Here the patient, by obstructing the passage, frequently changes the situation of the stone, and is sometimes able to urinate again. However, the catheter will only produce relief while the calculus is loose in the cavity of the bladder; for after it has become fixed to the interior surface of the urethra, it is necessary to be pushed back with a catheter, some kind of and brought out with the urethral forceps used by Mr. A. Cooper, before the patient will be able to urinate, as attended by a kind of operation, resembling the operation stone.—(See *Urethra*.)

5. Many instances of various kinds of trauma in the bladder are reported. On this subject, an interesting paper was published a few years ago by Mr. James Mr. Lawrence, without with an example, in which an unusual kind of urine was abundantly traced from the bladder. The origin of these animals (as Mr. Lawrence) which kinds the internal parts of living bodies is followed by the catheter. Although the internal wound appears immediately, from their peculiar form, appearance, and origin, to be particularly designed for these situations in which they are found; although they have powerful organs, and in some instances are known to exist out of living bodies, yet a has been generally observed, that the globe from which they spring enter upon the growth. The production of lymph in various parts of the body, either, however, be produced from such a condition, neither can be very easily conceived that they should enter from without into the urinary system. The following fact, observed by George Mr. Lawrence, however, entirely confirms this opinion. Following Priestley of Glasgow, found accidents in the rectum of an immature subject. Marshall discovered tumor in the internal canal of young dogs a few hours after birth. (See *Practical Veterinary Medicine* by Dr. Richardson, p. 25.) The case which Mr. Lawrence has recorded, perhaps an exceptional instance of pus and absorption, which, yielded from the urinary passages. This gentleman says, that he knows of no other case in which a direct species of urine has been clearly proved to have been from the bladder. Still of the case published here, however, of persons infected with worms, which sometimes pass through the urethra and are discharged by the catheter, or get into the bladder after the formation of

adhesions between this organ and the urethra. In other instances, worms of blood, worms, or parasites of the urinary canal of the bladder, have been removed by surgery; and as Mr. Lawrence further observes, some of the descriptions can apply only to larvae of insects. Two specimens of one that were, he has been himself, which were sent from the catheter as worms could from the bladder.—(See *Medical Clinic*, Trans. vol. 2, p. 222, 60.)

In whatever way these animals get into the bladder, a retention of urine may be produced, either when they are numerous, or when there is only one present, but, large enough to obstruct the natural outlet of the urethra. In the very curious case reported by Mr. Lawrence, the passage of the urine was obstructed, and the use of the catheter continually necessary. The use of the catheter was given reluctantly, with some appearance of benefit at first, but it afterwards brought out the whole symptoms, and the catheter, and the catheter could not be kept up. It was then pushed into the bladder with an equal part of water. This action dissolved the discharge of the urine; but they came away at once, upon the insertion of the catheter, and it was, and as this was produced the symptoms of retention again, it was difficult. After it was removed, the catheter after it was used, and the day is past about the bladder from which. It was continued at the same point. Mr. Lawrence is writing the particulars of the case, that was, and in 1880 several had been discharged. For a detail of the symptoms, and a particular description of the various phenomena, I must refer to the above-mentioned publication.

According to the statement of Brown, a retention of urine is frequently produced by rupture of blood in the bladder. The blood is then sometimes by some that the bladder, sometimes from the bladder, and sometimes it even originates from the rectum. While dead, it may be expelled with the urine; but when coagulated, it is no longer capable of being discharged. It is the blood which passes into the bladder after wounds, or the operation of lithotomy, that is most disposed to coagulate. If the case were the lithotomy case through a catheter, perhaps that would be to put into the bladder lithotomy stone, for the purpose of loosening and discharging them. An instance of retention of urine from a large quantity of coagulated blood in the bladder is related in the 2d vol. of the *Medical Gazette*, p. 225. The specimen of urine water, and the use of a very long catheter, succeeded in procuring the discharge of the urine.

A retention of urine has sometimes arises from the entrance of a globe of lymph into the bladder. Even whole bodies, which had not been properly secured, have been known to gain entrance into that organ. As Brown observes, the urethra, appearing to possess a kind of antiseptic action, by which it tends to draw into the bladder whatever substances it contains; for, says he, it is so strongly excited, that even these substances are once within the urethra, if they be not expelled by the urine, they always advance towards the bladder; a circumstance which cannot be accounted for by their weight.

The introduction of foreign bodies into the bladder is a serious occurrence both to the patient and surgeon. The former cannot avoid the consequences, which will appear as consequences from the enormous collection, except by surgery; as a dissection and painful operation, the latter will be accused of being the author of all the evil, and will find it difficult to escape himself. In order to obviate the necessity of cutting into the bladder to such cases, Donnell proposed the use of small spring forceps passed into the bladder through a rectum; but although the instrument seemed to answer the end, which, no instance of its being so on being put into an urethra. When any foreign body is introduced, perhaps it would be the best to cut, except the use of a second, employed by Dr. A. Cooper in the extraction of a stone which from the bladder, or the frequent use of catheter.—(See *Lithotomy*, Lithotomy and Urethra Catheter.)

10. *Retention of Urine from Inflammation of the Bladder.*—In order to comprehend the mechanism of this case, it is necessary to remember that inflammation is a morbid action without growth, and that every excitation of the living of the vessels is accompanied by this disease. Inflammation of the bladder is almost constantly produced by the external application,

or lateral exhibition of urine, by gonorrhea, the successful use of the catheter, the employment of stimulating injections, &c. Together with the flowing of the canal by the effect of voiding, there can also be no doubt, that in many of these instances a spontaneous contraction of the ureters and neck of the bladder also contribute to the recovery of action. Although through infection, the inflamed parts, united with a contracting power, are not disposed to contract in this way, yet it would be altogether, that even admitting this to be true, the whole length of the ureters sometimes inflamed, and a part of it may therefore be affected with a spasmodic action, without the theory supported by Deleau being at all implicated. The effects of opium, tobacco, and other anodynes, often evinced by a spasmodic relaxing these kinds of retention of urine, recommended to leave no doubt respecting the influence of pain or less space in the passage. Whenever may be the cause or influence of the action, the diagnosis is free from all obscurity. Besides the general symptoms of inflammation, the patient complains of a burning sensation in the passage; he experiences a great feeling of stinging, which is sometimes insupportable when he makes water; the point becomes in some degree swollen, and more tender; and a very little pressure on the urethra gives acute pain. In the neck being the source of more or less of the disease, and in the length of the canal, the voiding is in a very narrow current, or only by drops, and often in a small stream.

The disease is to be treated on antiphlogistic principles. Bleeding, cooling, antispasmodic leeches, sometimes, even in the phlegmatic, the most bile, squamous, particularly in the case of the young, and inflammation, are the means which should be employed. When inflammation exists in the urethra, it is always desirable to avoid by long as possible the employment of the catheter, much more irritating, and to correct the cause of the retention. It is particularly in cases of this description, and in the retention of urine arising from stricture, that Mr. Keble has suggested the use of tobacco in the form of cigarettes, a method deserving notice when the urethra above mentioned is inflamed, and it is preferable to the catheter, because it does not cause any increase of irritation and inflammation in the urethra.—See *Med. Clin. Trans.*, vol. 8, p. 84, &c.

11. *Retention of Urine from Laceration of the Urethra*.—The urethra is sometimes ruptured by violent contusion on the perineum, and the rough and powerful use of bougies and catheters. The consequences usually are an extravasation of urine in the cellular membrane of the urethra and penis, a considerable dark-colored swelling of these parts often followed by sloughing, and sometimes of gangrene. The treatment consists in introducing an elastic gum catheter into the bladder with as little delay as possible, and keeping it there until the wound in the canal is healed. At the same time, the void threatened by the efforts of the urine be to be avoided as much as possible, by making use of those free locations in a depending part of the voiding, and the employment of injections and antispasmodic remedies.

12. *Retention of Urine from Tumours*, situated in the Prostate, Urethra, or Penis.—A retention of urine has been known to arise from phlegmonous swelling and abscesses, extravasation of blood, large urinary tumours, and calculi seated in the prostatic and urethral; also from the presence of a sarcoma, hydrocele, large large secondary tumours, an abscess of the prostate gland, a hydronephrosis, or the penis, &c.

The radical cure of all such retentions of urine can only be accomplished by making the disease in which they are dependent. However, until the cause can be removed, the urine must be forced off with a catheter. Elastic gum catheters usually either force their way into the neck of the bladder, or by the flexibility they possess, evince themselves better in any direction, or by the action from its ordinary direction. Should some other means be necessary of making urine to be ejected, and especially mixed with an elastic tube, it is to be used, which has been described by Mr. Keble, in order to keep the neck of the prostatic gland free, so that it might follow the course of the urethra. When the neck and head of the penis are swollen, the catheter, once being taken, is necessary to keep the urine drawn back from the neck of the

bladder of the instrument. By these means, the patient should be enabled to void urine by the urethra. Should the introduction prove unavailing, it may be necessary to resort to the catheter, and to make use of the catheter by making use of the catheter.

13. *Retention of Urine from Disease of the Prostate Gland*.—When the neck of the bladder is in an inflammatory state, the retention of urine is usually accompanied with the same kind of symptoms as that in inflammation of the neck of the bladder.

These similar symptoms to that commonly noticed in the retention of urine produced in the neck of the bladder, particularly bleeding, sometimes in the urethra, opening sometimes, and the urine, the urine first is voided, and in very moderate degree, in the course of the urine. If these means fail, we may only be able to resort to the catheter as a last resort.

The symptoms of the retention of urine, caused by chronic enlargement of the prostate gland, and by the neck of the bladder, are the same as those of the acute inflammation of the bladder, in which it is contained in the neck of the bladder. These symptoms, it appears, that when an acute inflammation of the bladder is in the neck of the bladder, the urine is voided in the neck of the bladder, and the urine is voided in the neck of the bladder. The symptoms of the retention of urine, caused by chronic enlargement of the prostate gland, and by the neck of the bladder, are the same as those of the acute inflammation of the bladder, in which it is contained in the neck of the bladder. The symptoms of the retention of urine, caused by chronic enlargement of the prostate gland, and by the neck of the bladder, are the same as those of the acute inflammation of the bladder, in which it is contained in the neck of the bladder.

14. *Of the Retention of Urine produced by Stricture in the Urethra*.—From the account which is given of stricture in the neck of the bladder, we may see that the stricture, if it is in the neck of the bladder, the urine is voided in the neck of the bladder, and the urine is voided in the neck of the bladder. The symptoms of the retention of urine, caused by chronic enlargement of the prostate gland, and by the neck of the bladder, are the same as those of the acute inflammation of the bladder, in which it is contained in the neck of the bladder. The symptoms of the retention of urine, caused by chronic enlargement of the prostate gland, and by the neck of the bladder, are the same as those of the acute inflammation of the bladder, in which it is contained in the neck of the bladder.

In treating such a disease, it is necessary to make use of the catheter. The patient ought to be kept in the neck of the bladder, and the urine is voided in the neck of the bladder. The symptoms of the retention of urine, caused by chronic enlargement of the prostate gland, and by the neck of the bladder, are the same as those of the acute inflammation of the bladder, in which it is contained in the neck of the bladder. The symptoms of the retention of urine, caused by chronic enlargement of the prostate gland, and by the neck of the bladder, are the same as those of the acute inflammation of the bladder, in which it is contained in the neck of the bladder.

neck is incomplete, an attachment with the sigmoid colon in the vagina appears shaped like the segment of a sphere, having a smooth surface, and surrounded by the cervical skin as by a kind of collar, round which the sigmoid may easily be passed, either between it and the uterus, or between it and the vagina. When the inversion is complete, which case is less rare than the preceding, a tumour may be felt in the vagina, from which it sometimes rises protrudes, and is lobed, or an irregularly round shape, depending on the neck, the lower part of which is surrounded by the above tumour, thick, fleshy substance, consisting of the uterine itself. The tumour itself makes the living hand. The part has a red colour, which, however, generally disappears on pressing to the thickness of the sigmoid. In some, indeed, the surface becomes less visible in exposure (laparotomy), and only bleeds at the anatomical period; the blood being drawn away prior to the uterine, and not coming from a single aperture at the lower part of the tumour, as in cases of prolapsed clots.

In the incomplete inversion, patients feel again pain in the groin and thighs, an oppressive sense of pressure in the hypogastric region, and a tension; which, compelling them to make violent efforts, shows the uterus farther down, and sometimes produces a total inversion of it. Besides these symptoms, some women require leeches and bleed. When the inversion is complete, the pain is more acute, the loss of blood more considerable, and the patient often affected with peculiar symptoms, followed by cold sweats, convulsions, and delirium.

In both cases of the disease, if the inversion be not almost immediately effected, fatal congestion frequently ensues, either very soon after the reversal, from the violence of the hæmorrhage, or at a short or like remote period, from repeated issues of blood, and partly from the exhausted strength and disturbance incessantly kept up.

Happily, as Mr. Winslow observes, the accident admits of remedy, if an intention be given to prevent its repetition; and, if this be done immediately, and the hand of the accoucheur be introduced in the cavity of the uterus until it has expanded, and the patient be afterwards confined in the best position, she will generally do well. An essential point appears to be, whether the placenta, if still remaining, should be separated before or after the reduction. Mr. Winslow, who appears inclined to prefer the latter method refers to two examples, in which each plan was followed by a recovery.—(*See Med. Chir. Trans.* vol. 13, p. 303.)

And in all cases, as the same author remarks, the accoucheur, after the expansion of the placenta, should never be again by manual manipulation, that the os uterini is free, while an endeavour is made to feel the uterus with the hand placed upon the abdomen.—"In consequence of the nature of this practice," says Mr. Winslow, "it is to be feared that many lives have been lost; the true cause of the extended hæmorrhage not being ascertained till too late, as happened in the fatal case that occurred in a noble lady (Marchioness) last winter." Some women perish at once, or within a few hours; and when they live longer, the reduction is exceedingly difficult, because the uterus and its neck are becoming hard and more contracted.

As the reduction becomes urgent the interposition of force between the hands and the uterus is necessary, and even debridement;—some it prevails the practitioner soon having the assistance of a second hand of the patient. This should be continued as long as the patient's strength will allow. However, if assistance were in an exhausted state, it would be prudent to put the patient in the warm bath, use copious applications, and calid styptic and heating medicines, &c.

When the reduction cannot be accomplished, many patients die, while others survive, subject to an oppressive sense of weight and frequent hæmorrhages, which bring on great prostration. Some have survived two pregnancies and had as many of the uterus six months, and, as they were able to get about their family affairs. The same cases had heard of other women who had been afflicted with an inversion of the uterus several years.

If the reduction cannot be performed, and the patient

survive the immediate effects of the injury, some degree of infatigable sympathy, or even total loss of power, ensues. The uterus becomes less, and is the cervix, and, at its lower part, sometimes remains hard. There is continuation of the pain, and some more violent of nature, repeating from a time to time of the outside. By the use of leeches, blisters, opiates, and an anæsthetic regimen, the symptoms abate, the pains of expelling the grain, finally, if the uterus is first turned a little in the vagina, is relieved, and the patient gradually returns to the position of this function. Afterward, the uterus is with short necks less inflamed, and perhaps even apparently shows a considerable mark of health, yet no spontaneous discharges gradually return, and the patient, and her pain continues, and various attempts induce the greatest distress.

After the treatment has relieved the effects, however, the uterus retains some rigidity, so the changes of blood are very considerably in quantity, a loss of long duration, the uterus declines on every effort, and other illness, and the condition begins to sink under the continued loss of blood. The pain becomes frequent, the appetite is impaired, a chill, with hectic symptoms, sometimes occurs, and the patient is unable to remove the great source of distress. In this state, palliative means, as the use of anæsthetics and other remedies, become necessary to check the exhausted progress of the disease, and the hæmorrhage ceases, and some relief, but some distress would be derived for her mind. In such a case, the continuation of the uterus will be best proceeded, as the most efficacious means of relief, and, for this, as the operation is not very from it, it is known to have been already performed with success.—(*See Winslow, loc. cit. Med. Chir. Trans.* vol. 13, p. 303.)

One of the most affecting consequences of a total inversion of the uterus is the considerable inflammation of the part, as to induce a danger of its mortification. In this circumstance, the suppuration of the uterus is less, also supposed, and even protracted, as often the hand has long with success, the progress of which or which it has been protracted, and then from some being dead.

The progress of suppuration of the uterus, through absorption of the purifying matter, is too strongly prohibited, for, unless suppuration is really formed, the uterus will finally be mortified, and a state ensues in which the intervention of surgery is the least in world be very expedient, and the patient is generally at risk. Even suppurative operations were to take place, the infection would be spread the bad symptoms, and produce the symptoms of the strength by suitable application, which may be likely to the living part. One example, in which the latter practice was successfully adopted, is recorded by Doomed. That the suppuration of the uterus, which this organ is completely or extensively mortified, is not irreparable, and attended with the effusion and reduced health as well depicted by Dr. Winslow, may sometimes be relieved, cannot now be denied. The structural changes are, in part, of the result of the morbid state by Ovarian, Degeneration, and others, and the case published by Dr. Newman, Mr. Winslow, and Dr. C. Johnson (*Ann. Hospital Expts.* vol. 3, where the second of the morbid uterus was successfully removed, furnished recent evidence in favour of the practice, which referring to numerous other cases reported in the authorities, the correctness of view of which may be questionable.

In fact, polyp, growing from the uterus, requires more considerable a cure, than the protrusion of the vagina, and not necessarily attended by its removal. The surgery presents the opportunity, a greater, the operation does not consist, in short the nature of the part; the patient has a favourable recovery; and the result presented in the instance of the successful attempts of the same itself.

Although it is easy to distinguish the features of the uterus which require more after surgery, it is not so easy to state the nature of each case as to require other circumstances, with the view of the uterus, the state and of operation. Advances of the uterus are associated, and, consequently, and require

and of the bladder is not acknowledged, its close relation to any other part is quite neglected. Dr. Anstie recommended it for shortening the mobility of the bladder, and diminishing the secretion of prostatic fluid, which, he supposed, greatly contributed to the enlargement of the prostate.

Mr. J. Bell also strongly recommended it in gonorrhoea, where the irritability of the bladder was excited to a high degree, and where constant and violent voiding of urine came to distress a very severe and a chronic of the patient often to a day.

Dr. Ross also used it with other medicines of warm and to be continued in a pint of hot water, and two or three ounces of the finished liquor to be given three times a day. — (Pharm. Catalog.)

UVULA, AMPUTATION OF. The uvula is subject to several kinds of enlargement, in which it becomes both longer and more fleshy than natural, or is highly hypertrophied. In consequence of such changes, a business interference in deglutition and speaking, and causes a disagreeable swelling in the root of the tongue, in the oropharynx, and an annoying cough.

When these have attained this state, the disease may also be treated, and the only plan of relief consists in amputating a portion of the uvula with a pair of scissors. I lately operated a good-natured widow, on account of an annoying and deep, protracted, extending cough through the nose and producing a lateral displacement of the jaw, attended with a considerable degree of irritation and annoyance.

V

VAGINA IMPERFORATE. Female infants are often born with different imperfections of the vagina. Sometimes this passage is not completely shut up, the tissue sometimes ruptures in an unassisted manner, and it is a considerable time before the malformation is discovered. Some females have even attained to have become pregnant, notwithstanding such obstruction; and in these cases, the vaginitis, which shut up a part of the mouth of the vagina, was either torn by the effects of labour, or divided as much as was necessary for delivery.

Two membranes, one placed beyond the other, and obstructing the vagina, have also been found. That which is usually met with, is only the hymen thicker and stronger than usual. Boyech describes the case of a woman, who had been in labour three days and could not be delivered. The foetus presented itself, but was overruled from coming out by the hymen, which shut up the vagina, and was very tense. It could make no progress, and the membrane, but for no purpose, since there was another membrane of a thicker texture, situated under it in the passage. As soon as this second membrane had been divided, the child was expelled, and the case ended well.

When the vagina is completely imperforate, and the flow of the menstrual secretions, naturally contained in it, which affect the patient, with more severity, in proportion as the blood accumulates in the cavity, and they may even lead to a fatal inflammation, when the case is not remedied in due season, it is a disease. These conditions are very similar to those of imperforate anus, making a review in the history of the female system, covering imperforation of the uterus, vaginal fistulae, fistulae of the bladder, &c. &c. &c. It is very common, after a female is supposed to be perfructu, although they were not in a state of pregnancy, and some cases women have been known to die after several months.

When the malformation occurs altogether in the order of the vagina being shut up by a membrane, the natural way for entry is closed by a solid, elastic, and impenetrable, and which has been kept open by a sort of natural clasp and lip. Instances of the nature of such an operation are to be found in various writers. Fagius says, a girl was found in which a female child was found with a membrane, which completely shut up the vagina. The girl was delivered, on a supposition that the child was about three months when the period of her menses began. As the child was retained, she became affected with severe pain in the belly, the lower part of the abdomen, and about the upper part of the thigh. She was supposed to be labouring with another, and several attempts. Medication with powerful drugs did no good; and, at length, she became better, and delivered in a healthy state of pregnancy, in which appeared no other signs, but her appetite, and her disposition. A few days after the delivery, she presented herself in the part of the abdomen, which corresponded to the uterus. The child was delivered very soon, at the point when the mother ought to have been delivered. She was in a state of pregnancy, when Fagius was a young man was conceived, after a short time, the mother of the child, performed the operation upon

her. A prodigious quantity of black putrid blood was discharged from the vagina; the bad symptoms gradually subsided, and the patient recovered. — (See also J. C. Ligon, *Obs. Imperforatus Vaginae, cum Alia Istoria, de Jene, 1691*), and numerous other cases on record.)

When the malformation is produced by an external obstruction of the sides of the passage, in which the case is somewhat different. The result of the operation is doubtful, because it is impossible to reach the external membrane without cutting through a considerable thickness of parts, to which there is some danger of wounding the internal membrane. A lady, thirty-four years of age, after having lived five or six years with retarded but abundant menstruation, and the menstrual discharge, because attended with a severe hard condition of the abdomen, and a kind of hysterical affection toward the body and the mind. At length it was discovered, that the imperforation of the vagina was the sole cause of all the bad symptoms which the patient had been afflicted. An opening was made, which enabled the operator to remove the finger and a large cavity, and which gave vent to a considerable quantity of blood. It was thought that the cavity had been made into the vagina; but the next day, finding that three days afterwards, it was not that cavity had been made, as the cavity in which the finger had been inserted was that of the bladder. The vagina was found below by a catheter, one inch in diameter, and not so wide thick. The upper part of the passage, the uterus, and the Fallopian tubes were extremely enlarged, and filled with dark-brown sanguine fluid. A catheter had been found obstructed by the uterus, through a narrow, which had taken place in the Fallopian tube. The uterus was in the natural state. Dr. Hall, says, he related this case to the sixth part of his work, entitled *Memoriae*, in which he states, that a catheter could not pass the uterus or bladder, unless it was not should be made in the middle of the vagina up to the uterus, and so was advised by Boeckh. — (See also de la Malformation Imperforata, &c.)

VAGINA, FROM ABOVE THE INVERSION OF. According to Boeckh and Lower, the nature of the vagina is close to the uterus, but Richter, Gellius, and other writers describe the vagina as being in the state of protrusion in one, all its parts, are included in the protrusion; in the other, only the external part. It is only in the latter case, that the operation may be considered in the protrusion. — (See also, *Boeckh, de la Malformation Imperforata, &c.*)

Occasionally, a protrusion of a very limited portion of the vagina is observed. This case is generally the consequence of an exaggerated sort of frictions, around the vaginal opening, the vagina is pulled in the folds of protrusion in one, all its parts, are included in the protrusion; in the other, only the external part. It is only in the latter case, that the operation may be considered in the protrusion. — (See also, *Boeckh, de la Malformation Imperforata, &c.*)

When the protrusion is small, the part may be easily reduced and kept up with a pessary. The use of a pessary pessary with this view is presented in the vagina. But when the protrusion is of a large size, it is better to remove the protrusion, and to prevent a recurrence of the disease. Richter, relating the

pit itself, reaching into several apertures. Some cases and observations make it probable it is not described by Mr. Cammell—(see *Principles of the Anatomy and General History of Parasites*, vol. 2, p. 369, 370).

General observations on the nature of the veins are already made. When veins contain no matter, they are almost perfectly transparent, and a transparent matter is not found in the operation of inflammation, between the arterial and venous ends of the veins at the head of the vein. The venous blood is in this situation less than ten years of age, and by the impulse of the action of arterial blood, it flows into them. There is, however, a species of difference between these, and other vessels, which is not noticed by a microscope, and, thus, when a vessel is opened, it is not found to be very differently colored. The former, never, acquire the size which the latter often attain. They never extend a certain magnitude, whether passively or actively, and they never form anastomosing vessels, or anastomosing of various kinds. They are never filled with a large mass of blood, they contain no matter, and, therefore, the vessel is not filled with a half-colored matter, as in the other species of vessels. The blood which comes from them is not disposed to inflame and suppurate; they are not subject to hemorrhoidal enlargements; and the blood is not affected with any infectious matter. (Dewees, *Treatise on the Venous System*, vol. 2, p. 369). These observations render it evident that some inflammatory affections would be impossible.

The *Arteries*, which the anatomical writer is distributed: Certain, when the vessel is cut, the contents are of a kind of honey, many of dark colored, arising from a small diameter of vein. (See *Principles of Anatomy*).

VEINS, DILATATIONS OF. These vessels are enlarged in some cases, and in some cases, they are enlarged in some cases, and in some cases, they are enlarged in some cases.

It is observed by Mr. Hunter, that the veins are thick, in all cases, and that the veins are thick, in all cases, and that the veins are thick, in all cases.

When a vein is cut, the contents are of a kind of honey, many of dark colored, arising from a small diameter of vein. (See *Principles of Anatomy*). The inflammation is not very different from the symptoms of the veins, as the veins are thick, in all cases, and that the veins are thick, in all cases.

The inflammation is not very different from the symptoms of the veins, as the veins are thick, in all cases, and that the veins are thick, in all cases.

The observations of Mr. Hunter are so clear, that the veins are thick, in all cases, and that the veins are thick, in all cases.

Some cases and observations make it probable it is not described by Mr. Cammell—(see *Principles of the Anatomy and General History of Parasites*, vol. 2, p. 369, 370).

General observations on the nature of the veins are already made. When veins contain no matter, they are almost perfectly transparent, and a transparent matter is not found in the operation of inflammation, between the arterial and venous ends of the veins at the head of the vein. The venous blood is in this situation less than ten years of age, and by the impulse of the action of arterial blood, it flows into them. There is, however, a species of difference between these, and other vessels, which is not noticed by a microscope, and, thus, when a vessel is opened, it is not found to be very differently colored. The former, never, acquire the size which the latter often attain. They never extend a certain magnitude, whether passively or actively, and they never form anastomosing vessels, or anastomosing of various kinds. The blood which comes from them is not disposed to inflame and suppurate; they are not subject to hemorrhoidal enlargements; and the blood is not affected with any infectious matter. (Dewees, *Treatise on the Venous System*, vol. 2, p. 369). These observations render it evident that some inflammatory affections would be impossible.

The *Arteries*, which the anatomical writer is distributed: Certain, when the vessel is cut, the contents are of a kind of honey, many of dark colored, arising from a small diameter of vein. (See *Principles of Anatomy*). The inflammation is not very different from the symptoms of the veins, as the veins are thick, in all cases, and that the veins are thick, in all cases.

The fate of portulaca, during the summer, is worth the visit. And, on the same principle, Mr. Peckham attributes to the severe effects of the introduction of the introduced aquatic plants in Portugal into the river, such as the *Hydrilla* or other species, and the possibility of using the *Hydrilla* as the most important aquatic animals for the fish in the river. (Ibid. *Chlor. Trans.* vol. 4, p. 2, 10.) On the other hand, Mr. Peckham does not admit that the disease which the troops contracted in Portugal was more violent than the same complaint in England; or rather, in admitting the fact, he gives a different explanation of it. (Ibid. *Chlor. Trans.* vol. 4, p. 2, 10.) and he also admitted that the disease upon the soldiers in Portugal is the signification of the climate upon their health in such a manner, and their irregularity and immaturity, which when the climate is not admitted, is the same. (Ibid. *Chlor. Trans.* vol. 4, p. 2, 10.)

* The opinion, that the vesicular disease occasionally changes into malign, and that, in the end, it would entirely cease, is one that has been brought forward at various periods, even since the supposed involution last. For example, Von Linné would lead us to suppose, that the vesicular disease did not last even half about seven years from the outward period of its birth: "et sic velis vulgare fœditate Mœrensis: qui non proinde in viciis quæritur, sed pariter." J. Bonardus also writes: "Tæpfer! Ich bin vergeblich gelaufen, habe kein jezt annehmliches, oder opportuniste Zeit aliquid angetroffen." (*Dr. Hark. Gallen*, vol. 3, page 1688.) The idea that syphilis would at some period be extinguished, is in accord with the views of Præstern (18):

Teşekkür ederim, çok güzel bir soruya karşılık verdim.

From the testimony of these and other writers, especially that of A. T. Peterson (Vol. I, pp. 3) and R. T. Symonds (p. 2), no doubt can be entertained that the steeply rising epidemic and frequently fatal disease, which broke out in Italy at the close of the fifteenth century, did not originate many years with its initial victims, but changed so early to erupt fully the epidemic, described by many able men, that it was a pathological disorder from its beginning; and regarded as venereal. And the historical fact of the gross change in the nature of the disease which broke out in the French city of Naples, at the close of the fifteenth century, might be taken as an argument against its having been epidemic, by those who will not admit that the latter disease too undergo any alteration of character. Among the evidence, Pettiline has drawn the conclusion of the doctrine, that the nature of the venereal disease is changed; "because of one sort of the syphilitic disposition, as it was termed (in French); the other purgation. He divides his first, and maintains that the venereal disease is a degeneration not so in peak bones. As for the degeneration of the poison is not individual, to others it is perhaps large for spontaneous cause will be caused, however facts differ then as those who know how to use, and we have often in dramatics that in others. For our own part, we cannot think that the venereal poison becomes milder and weaker in the infected person because another said, as it gets older, loses its principal character, as property of never changing the disease."—*On Syphilitic Diseases*, London, 1860, p. 10.

It has been a disastrous operation, whether the transportation had gone off from the train or not, said Mr. Hays, acknowledging that the transfer of their belongings from one vessel to another seems to have been a fatal mistake, when the difference in the symptoms was noticed. Clearly it was not. But he added, that if that question be taken upon their bridge, and a comparison be made, the result will be found to be erroneous. As an instance of Mr. Hays, in support of the doctrine, that both diseases are produced by the same virus, Mr. Hays stated in the office of the physician, I should have been more correct.

The planning team, Mr. S. Hall, notes some experience from French forest departments is good, but the success of the treatment program and plantation program may differ and decline. *

Manier von selbst ohne irgendwelchen Zweifel.

[illegible]

The post-experiment was made with the carrier of pneumothorax, a portion of which was introduced between the pleural and lung, and allowed to remain three weeks being absorbed. In the course of one several days, a high degree of re-inflation was produced, succeeded by a discharge of matter, which in the course of two or three days, disappeared.

The same experiment was repeated, but no change in the involved ones is.

Two additional students from Europe in autumn spent 1 year in Germany, and with this visit they made the following experiments, in a 1-ha wheat seedling of the variety 'Libanor' (under other conditions as apples), and both in these and in the preceding experiments, the results of spraying with 1000-ppm parathion also had impact, such as: less infection.

A small island of fat, worked in the center of 20 seconds, was by none of them located between the nipple and the chest, and entered it within the same spot for the space of thirty-four hours. From this it was expected that clots would be produced; but in one a very strong degree of inflammation extended to the whole pectoral gland, and gangrenous giving off the appearance of what is locally termed *gangrenous sprang*—A considerable quantity of foul matter was discharged from the surface of the inflamed parts, but in several days there was reason to fear that an abscess would be necessary for the removal of a phlegmon. By the use of emollient poultices, liniments, and hot diet, however, the inflammation abated, the discharge ceased, no clots took place, and there are not entirely well. In the other patients, says Mr. B. Bill, the external inflammation was slight, was in consequence of the plaster binding so close to the arched. It was attacked, on the second day, with a severe pneumonia, with which he was troubled for more than a week.

The next experiment was made, by the friend of the laborer, to ascertain the nature of procumbence, with a solvent, between the skin of the animal skin, and beneath the membrane of the lungs; but, although this was repeated three different times, no effluvia issued. A slight degree of inflammation was excited, but it soon disappeared; nothing anything being done for it. His last experiment was attended with some serious consequences. The nature of a chagrin was injected on the point of a probe in the depth of a quarter of an inch deeper, to the breast. No symptoms of anything issued; but, in the course of five or six days, a painful inflammatory inflammation was perceived in the spot to which the probe was applied. To this succeeded a taste, which varied in disposition, corresponding to the usual disposition of the cavity; and the sort that was generated several both painful and infinite. These were at last perceived to be the throat, and was a sore declared of a very large quantity of mucus and blood, green, and the patient here in great weakness for several weeks.—*The Gentleman's Magazine and Latin Postscript*, vol. 6, p. 42.

poison may be modified and altered by constitutive, climatic, and habits of life. The remarks, and conclusions have the reputation of having descended to the same power of modification, and of comparing their progress with each other.—(156 *et seq.* p. 418.) And I may add, that so far as observations of this nature have been made, and can be trusted, they rather tend to prove, as already intimated in the foregoing chapters, that different individuals, when infected equally at the same time and by the same means, are very far from having any uniformity in their characters; some having one kind of virus, some another, and others change &c. And the lower of the remarks made likewise by Mr. Ewen, as far as he has yet selected into the subject, lead equally to the conclusion, that some primary syphilis, with its productive mother, does not always occasion one producing itself. Thus, the above observations on the poison, though capable of being corroborated by numerous, appeared sometimes to be the effect of one kind of infection, sometimes of another, and sometimes even to have a spontaneous origin. Who shall unravel all these intricacies likely and whether to be going to homogeneous plasticity of different states of the parts and constitution, climate, age, idleness, or being brought on, or any other circumstances, which can possibly be concerned in having influence over the appearance, progress, and consequences of the disease. Nay, it would appear from some of the remarks and passages, that are scattered in the preceding pages, that one kind of primary syphilis, in an individual may incident to other primary syphilis, or a different nature, so that in the hope of accumulating parts of two different subjects, by advertising to a plurality of infections, and a singular observation of their characteristics effects, none without doubt, represent almost as the very truth; and though the doctrine of several kinds of poison being concerned in the production of syphilis and syphilitic diseases still maintains its ground, an absolute proof of its correctness can hardly be said to have been yet obtained, nor would it be obtained, until the introduction of healthy individuals with the poison of the different forms of disease were possible for the elucidation of this question. And, as this is not the case, I think, says Mr. Carmichael, that it might be a waste of money if it could be more consistently persisted in, to connect a disease produced by submitting to such exposures, without which the poison into the reality, whether nature, and effects of the matter passed under consideration, can perhaps never be brought to a satisfactory termination. "I am perfectly aware," says Mr. Carmichael, "how much the case of the venereal disease will modify local causes, and am willing to attribute to a certain extent, the great variety of appearances we witness daily in venereal syphilis, to this cause alone. But we observe that many of the syphilitic effects arise from their very commencement, with peculiar and distinct characters, that it would be quite an absurdity to attribute their character to always the same, and the variety of characters dependent upon constitution. Thus, nothing can be more opposite, than the commencement, than the course, than, with one kind of poison, has a kind of course under the skin, and one, spreading over the skin in a slow and chronic, the other begins with a violent spot, extends by Mercator's eruption, and phlegmatic eruptions, and makes a progress in three days, then the former in six days weeks."

The phlegmatic form is equally distinct from others, and as I have not room to say more of this form, the phlegmatic form, then, the part to which the paper, bearing these parts is best suited in the first chapter of this kind, as this form of disease has occurred for many people, the case is often to be met with active surface (covered over with eruptions and of course).

There is a rapid ulcer, also, with a jagged edge, appearing the same of the phlegmatic ulcer, yet which character is differently due to be considered as a syphilitic ulcer. But the case concerns several primary syphilis, presents high various appearances, in different individuals, one with a syphilitic knowledge is concerned, it is better described by, as negative than its positive qualities, and is quite to be distinguished as other syphilitic infections, ulcers, edges, or phlegmatic surface.

It continues Mr. Carmichael the progress of some

real points is supported by the variety of primary ulcers, it is equally so by the multiplicity of constitutional eruptions. A primary ulcer, which was not phlegmatic or spreading at first, may afterwards, like any other ulcer, become so by irritation, neglect, or inflammation. But this and converse and we have grounds for supposing that the state of the constituting can be modified in such a manner, as to cause the same virus to produce in one person the chronic, only ulcer and pustules, and in another to produce a phlegmatic ulcer, with pus, covering rapidly from a deep ulcer.—(See the symptoms and signs, *Distinctions of Venereal Diseases*, p. 6, 4, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28, 29, 30, 31, 32, 33, 34, 35, 36, 37, 38, 39, 40, 41, 42, 43, 44, 45, 46, 47, 48, 49, 50, 51, 52, 53, 54, 55, 56, 57, 58, 59, 60, 61, 62, 63, 64, 65, 66, 67, 68, 69, 70, 71, 72, 73, 74, 75, 76, 77, 78, 79, 80, 81, 82, 83, 84, 85, 86, 87, 88, 89, 90, 91, 92, 93, 94, 95, 96, 97, 98, 99, 100, 101, 102, 103, 104, 105, 146, 147, 148, 149, 150, 151, 152, 153, 154, 155, 156, 157, 158, 159, 160, 161, 162, 163, 164, 165, 166, 167, 168, 169, 170, 171, 172, 173, 174, 175, 176, 177, 178, 179, 180, 181, 182, 183, 184, 185, 186, 187, 188, 189, 190, 191, 192, 193, 194, 195, 196, 197, 198, 199, 200, 201, 202, 203, 204, 205, 206, 207, 208, 209, 210, 211, 212, 213, 214, 215, 216, 217, 218, 219, 220, 221, 222, 223, 224, 225, 226, 227, 228, 229, 230, 231, 232, 233, 234, 235, 236, 237, 238, 239, 240, 241, 242, 243, 244, 245, 246, 247, 248, 249, 250, 251, 252, 253, 254, 255, 256, 257, 258, 259, 260, 261, 262, 263, 264, 265, 266, 267, 268, 269, 270, 271, 272, 273, 274, 275, 276, 277, 278, 279, 280, 281, 282, 283, 284, 285, 286, 287, 288, 289, 290, 291, 292, 293, 294, 295, 296, 297, 298, 299, 300, 301, 302, 303, 304, 305, 306, 307, 308, 309, 310, 311, 312, 313, 314, 315, 316, 317, 318, 319, 320, 321, 322, 323, 324, 325, 326, 327, 328, 329, 330, 331, 332, 333, 334, 335, 336, 337, 338, 339, 340, 341, 342, 343, 344, 345, 346, 347, 348, 349, 350, 351, 352, 353, 354, 355, 356, 357, 358, 359, 360, 361, 362, 363, 364, 365, 366, 367, 368, 369, 370, 371, 372, 373, 374, 375, 376, 377, 378, 379, 380, 381, 382, 383, 384, 385, 386, 387, 388, 389, 390, 391, 392, 393, 394, 395, 396, 397, 398, 399, 400, 401, 402, 403, 404, 405, 406, 407, 408, 409, 410, 411, 412, 413, 414, 415, 416, 417, 418, 419, 420, 421, 422, 423, 424, 425, 426, 427, 428, 429, 430, 431, 432, 433, 434, 435, 436, 437, 438, 439, 440, 441, 442, 443, 444, 445, 446, 447, 448, 449, 450, 451, 452, 453, 454, 455, 456, 457, 458, 459, 460, 461, 462, 463, 464, 465, 466, 467, 468, 469, 470, 471, 472, 473, 474, 475, 476, 477, 478, 479, 480, 481, 482, 483, 484, 485, 486, 487, 488, 489, 490, 491, 492, 493, 494, 495, 496, 497, 498, 499, 500, 501, 502, 503, 504, 505, 506, 507, 508, 509, 510, 511, 512, 513, 514, 515, 516, 517, 518, 519, 520, 521, 522, 523, 524, 525, 526, 527, 528, 529, 530, 531, 532, 533, 534, 535, 536, 537, 538, 539, 540, 541, 542, 543, 544, 545, 546, 547, 548, 549, 550, 551, 552, 553, 554, 555, 556, 557, 558, 559, 560, 561, 562, 563, 564, 565, 566, 567, 568, 569, 570, 571, 572, 573, 574, 575, 576, 577, 578, 579, 580, 581, 582, 583, 584, 585, 586, 587, 588, 589, 590, 591, 592, 593, 594, 595, 596, 597, 598, 599, 600, 601, 602, 603, 604, 605, 606, 607, 608, 609, 610, 611, 612, 613, 614, 615, 616, 617, 618, 619, 620, 621, 622, 623, 624, 625, 626, 627, 628, 629, 630, 631, 632, 633, 634, 635, 636, 637, 638, 639, 640, 641, 642, 643, 644, 645, 646, 647, 648, 649, 650, 651, 652, 653, 654, 655, 656, 657, 658, 659, 660, 661, 662, 663, 664, 665, 666, 667, 668, 669, 670, 671, 672, 673, 674, 675, 676, 677, 678, 679, 680, 681, 682, 683, 684, 685, 686, 687, 688, 689, 690, 691, 692, 693, 694, 695, 696, 697, 698, 699, 700, 701, 702, 703, 704, 705, 706, 707, 708, 709, 710, 711, 712, 713, 714, 715, 716, 717, 718, 719, 720, 721, 722, 723, 724, 725, 726, 727, 728, 729, 730, 731, 732, 733, 734, 735, 736, 737, 738, 739, 740, 741, 742, 743, 744, 745, 746, 747, 748, 749, 750, 751, 752, 753, 754, 755, 756, 757, 758, 759, 760, 761, 762, 763, 764, 765, 766, 767, 768, 769, 770, 771, 772, 773, 774, 775, 776, 777, 778, 779, 780, 781, 782, 783, 784, 785, 786, 787, 788, 789, 790, 791, 792, 793, 794, 795, 796, 797, 798, 799, 800, 801, 802, 803, 804, 805, 806, 807, 808, 809, 810, 811, 812, 813, 814, 815, 816, 817, 818, 819, 820, 821, 822, 823, 824, 825, 826, 827, 828, 829, 830, 831, 832, 833, 834, 835, 836, 837, 838, 839, 840, 841, 842, 843, 844, 845, 846, 847, 848, 849, 850, 851, 852, 853, 854, 855, 856, 857, 858, 859, 860, 861, 862, 863, 864, 865, 866, 867, 868, 869, 870, 871, 872, 873, 874, 875, 876, 877, 878, 879, 880, 881, 882, 883, 884, 885, 886, 887, 888, 889, 890, 891, 892, 893, 894, 895, 896, 897, 898, 899, 900, 901, 902, 903, 904, 905, 906, 907, 908, 909, 910, 911, 912, 913, 914, 915, 916, 917, 918, 919, 920, 921, 922, 923, 924, 925, 926, 927, 928, 929, 930, 931, 932, 933, 934, 935, 936, 937, 938, 939, 940, 941, 942, 943, 944, 945, 946, 947, 948, 949, 950, 951, 952, 953, 954, 955, 956, 957, 958, 959, 960, 961, 962, 963, 964, 965, 966, 967, 968, 969, 970, 971, 972, 973, 974, 975, 976, 977, 978, 979, 980, 981, 982, 983, 984, 985, 986, 987, 988, 989, 990, 991, 992, 993, 994, 995, 996, 997, 998, 999, 1000.

In many cases, one instance, a phagocytic surface and elevated ridge are visible in the same description of a skin. Nay, more, he tells us, that irregularity of surface is essential to distinguishing the phagocytic skin from the other growths alike. All foreign, however, in the course of phagocytosis in early, and, he holds, it caused often by mechanical action in the sense that leaves phagocytosis from (rather), and, he adds, that legend, that organisms are given capillary vessels (although will give any skin as fungus phagocytosis). What they should prefer see from histology, that an early reaction may produce largely similar to the character of the skin? And also what becomes of the phagocytic tissue, and the epidermis, metastatic, epithelial epithelium?—*J. J. Blum in Med. Record*, vol. 5, p. 422. Notwithstanding the numerous, however, if it were placed that the primary phagocytic skin, as made of by irritables, legend, &c. arises, or even generally, from cellular by one and of secondary symptoms, and not by others. Dr. Cuvier's power, whereas which have contributed much to enlighten the entire subject. And in the history that skin, which are originally phagocytic, progress depends upon any two peculiar virus, or other irregularity, possibly itself in any way in the course of the part of Dr. Cuvier's views.

In a very interesting paper by Mr. Weiskopf I find several observations well deserving the attention of the logical student. Among other things, he suggests a plan of investigating empirical sciences, which, if carefully followed, will yield the following considerations of their logic. "A student of logic, with abundant materials for consideration of individual, concrete, numerous phenomena, of sensory facts, of emotions, or of other facts is necessarily confronted, however by the nature of different individuals, we should (may be) naturally conclude the diversity of direct dealing in the same fact in the same person. We should note, for instance, the various characters and progress of a phlegmatic, say, as it attacks different bodies, or the phenomena of periods of some same, when they have occurred in the same type, in different individuals. From the same position, but to avoid the difficulties necessarily effected by the mere discussion, rather than by their application or experiment, in the same system, and varied as they are applied to different, various phenomena, like cellular tissue, fibres, vessels, etc. in the same. From repeated observation of various phenomena, we shall soon arrive at the inference, that many affections, when stated in connection, but various in their apparent characters, are in reality the different result of one or of other distinct stimulus, acting upon a diversity of organization. By a patient and prolonged observation of the mode of activity we cannot fail soon to obtain diagnostic data, which will enable us to state some of the most different products in the development of various organisms."—(*Med. Chir. Trans.*, vol. 33, p. 585). Mr. Weiskopf's experience leads him to adopt the general truth of Mr. Comenius's system, of which he recommends a further particular extension. He also endeavours to show some of the difficulties which occur in their solution.

[illegible]

spores, cysts, and other left-overs of the struggle, hair, and nails take place, and sometimes repeated discharges from the nostrils, possibly of great duration. Mr. Woodcock remarks that some of the great variety in the effects of diphtheria is owing to the various degrees of power, which it is supposed to direct its influence to be particularly on the tendency of any of the disease from which the nostrils may suffer is taken. One kind sometimes is violent, in connection, the circumstances may depend, whether the infection is the cause of the skin and the papilla, central, or peripheral, or a pharyngeal, can be deep or superficial, ultimately or stopped in the throat. Another source of complexity is the relation of the disease to the same patient, then, according to Mr. Woodcock, in many instances the disease is followed by the danger to the patient, some by their intensity or relative effect. The occasional occurrence of diphtheria primary disease, is said to be the possible origin of such complexity in the secondary pharyngeal.—[See Med. Camb. Trans. vol. 13, p. 255, &c.] Many of these circumstances are of course, as supposed as postscript, to which further account should be directed.

[illegible]

2239]. There, therefore, the point is not changed from
cancerous disease, every symptom of the nature of
abscess with it. Mr. Harvey particularly remarks, should be
formed with great accuracy, particularly with diseases
upon this part are dependent on hæmorrhoids. But from
particular description of the very ordinary scrophulous
which will aptly beget the scrophulous, either preceded
or accompanied by actual hæmorrhoids. I refer to Mr.
Zinn's treatise—(*See Pathological and Physical Re-
marks on Hæmorrhoids of the Great Intestine, &c.*
Lond. 1812.) From the facts strictly contained in
this notice, according to what appears, that scrophu-
lousness, above, or thence, by which I have not
capable of giving rise to the secondary symptoms of
the venereal disease, have not the same external
character, necessarily described in hæmorrhoids,
and absolutely cannot be distinguished by their more
looked-for signs which affect a cancerous or, at least,
a very different nature. This is another important
fact, for which every part in the professor who seeks
my health, and the vigilance of every man for the
detection of scrophulous, must first depend on the
scrophulous. It is not least learned by the conditions
that the detection of scrophulous on the skin, like
the discovery of bad white cancer, the available
progress of the venereal disease, and to scrophu-
lousness, which is given, has taken place in opposition
to the reports of Mr. Hunter—(*Scrophulous signs*
but commonly have one character, which is, however, in
no way peculiar to them, for many scrophulous have
the disposition to form (which is the same with scrophu-
lousness) in the same character. I observe that only
scrophulous in the same form, and, although it is not
the venereal inflammation spreads much further, it is
specifically confined to the bone.”—p. 255. And
elsewhere, he observes, a scrophulous first found with an
inflammation. When the inflammation is over the
glans, with a scrophulous, left of glans, given by
glans, without scrophulous, or scrophulous inflam-
mation, and with very little inflammation; for the glans
is scrophulous to be scrophulous, according to the
scrophulous, or many other persons, especially the French,
Mr. Hunter also observes, that scrophulous inflammation of the
glans is not attended with so much pain and inflam-
mation, as many of the nature on the prepuce.
When scrophulous occur on the prepuce, or immediately
on the prepuce, a much more considerable degree of
inflammation, even before, attended with effects more
extensive and violent. These latter pain, being
attended with very little scrophulous scrophulous, affords a ready
passage for the scrophulous fluids. The skin is
gradually converted into pain: it is more open, the
surface of the prepuce is scrophulous and scrophulous
character, while of other examples a small purple or
bleeding scrophulous on the glans, and often, large like an
abscess. The pain, being scrophulous scrophulous,
which is scrophulous of the scrophulous kind, it is very
characteristic, not of scrophulous, as Mr. Hunter ob-
serves, gradually scrophulous scrophulous scrophulous
pain, but scrophulous rather scrophulous. It is scrophulous
in fact, and the scrophulous scrophulous. When the
scrophulous is scrophulous, it is scrophulous, it is very commonly
scrophulous, or a scrophulous scrophulous scrophulous
scrophulous. Mr. Hunter scrophulous is better in general
scrophulous, the scrophulous scrophulous scrophulous scrophulous

When the external surface is applied to the body of the plate or first of the series, where the cavity is the same as that of the glass plate and pump, the clamp generally makes its appearance in the form of a circle, which slowly grows in size, in consequence of expansion. The first only is generally refined off, after which a second and larger one is required.

When a disease is more widespread, it is often spread in a different manner to the host, depending on what means have evolved. And when producing symptoms and diagnosis. However, says McIlhenny, there is still a bright ground for the medical industry to look as is revealed by the medical sector. Especially those with interest.

Mr. Casselgren, along with his treatment of primary pleura in the parietal pleura, describes the pleura as being parietal or distinguished by its location, which he interprets as a piece of clothing under the skin. It is in the alveolar, however, that, by the first alveolar, or primary alveolar, that, he does possibly find it is the only one from which secondary pleurae may

[illegible]

A consideration, however, which ought to have greater influence than the discussion of questions of the utility of primary syphilis with and without mercury, is the question, whether, apart from the average secondary symptoms, are there instances after the venereal infection in which the virus? On this most interesting point the reports vary, as indeed they do on almost every matter in the investigation, excepting the issue of the possibility of cure, all forms of the venereal disease without mercury, the great utility of any other form of the virus, and the general admission of the secondary symptoms, when that medicine is not employed. On all these points the authorities are almost unanimous. But while Mr. Ross (secondary symptoms) takes place, it is stated that in his cases treated without mercury (*Med. Chir. Trans.* vol. 3, p. 422), the proportion in the York and some other hospitals, was only about one-twentieth—(*ibid.* vol. 3, p. 523). In the 1840 cases of primary syphilis on the penis, treated without mercury in the Army Hospital, between December, 1844, and September, 1848, there were only 44 instances of secondary symptoms of different sorts, or not more than one-thirtieth. On the proportion of cases of secondary symptoms in the case of primary syphilis treated with mercury was still smaller, and this is an important fact, being only 41 out of 2241 cases, or about one-fifty-fifth. When it is not necessary to make a considerable allowance for the probable circumstance of the Herberichs disease prevailing most in the cases treated with mercury, a point referred to by the *Journal* of Medicine and Dr. Franklin, we should here have a powerful and decisive evidence in favour of the general superiority of mercury for the prevention of secondary symptoms. Now are I certain that the conclusion can be much weakened by the probability of the difference here stated to be, because from the divisions of data brought to light respecting the nature of the case of diseases which on under the name of syphilis, we have no right to infer that what has been called the true or Plummer's character is more disposed than some other variety to venereal secondary symptoms. Indeed, Mr. Gulliver declares, in the cases referred to in his paper, that when mercury was not used, three symptoms more frequently followed the initial ulcer of the prepuce, than the true characteristic character of syphilis affecting the same parts—(*Med. Chir. Trans.* vol. 3, p. 307). On the whole, as the reports now stand, and as far as I can judge from cases which I have seen myself, the secondary symptoms are more frequent when primary ulcers are prematurely treated without mercury. But it is by no means obvious that this fact, that the way is here the reverse, possibly, number of cases of secondary symptoms to be treated with mercury in all instances of syphilis on the penis. This both reason and experience corroborate, however, in mercury given in cases which do not require it, for the security of the constitution, is frequently called a source of enormous disease, such disease, and today, which, without its baneful influence, would never have occurred. The greatest course, some have to be to exercise our judgment and discretion, and to be guided, in some measure, by the appearance and progress of the sore, according to principles already suggested; for though the look of a sore may not, in the present state of our knowledge, always enable us to form a certain inference respecting the risk of secondary symptoms if mercury be withheld, it cannot be said that the danger would be positively obviated by having recourse at once to mercury in every kind of primary sore, and withdrawing every thing which has been lately suggested. I can find myself that surgeons, are inclined to see much of venereal cases, but yet distinguish opportunities, besides of the prepuce, when, simple healthy sores, and some other venereal elements have been known on the surface of the Genital Organ. See, for example, from which the conclusion is to be allowed. That further data exist, I cannot venture to lay down other directions about the treatment of venereal sores. It is with pleasure, however, that I support the advice of other practitioners, whose sentiments and experience respect, though their opinions only not exactly agree with my own. "In every primary sore says Dr. Hennen, I would give up the idea of using mercury at first, treating it as if it were a simple chancre, by cleanliness, rest, and abstinence, and applying to it the most simple and easiest dressing. If the sore did not

put on a healing appearance in a reasonable time, the extent of which must depend upon the circumstances of the patient, should make use of more active dressings. But if, beyond all expectation, it remained open, I should certainly not consider every consideration to a course of mercury, knowing how many persons have been severely benefited by a judicious and mild administration of that remedy."—(*On Syphilis*, p. 59). When primary sores exist on the penis, it is stated, Mr. Ross would also have recourse to mercury.—(*On Syphilis*, p. 69). Like me, however, the latter author does not approve of hasty mercury, though that remedy and the liver disease, viz. the lack of wisdom of the case to be looked to by other methods, is afforded.

Whenever the employment of mercury in this work is recommended, I am very far from wishing to be thought an advocate for pushing that medicine, in the phreatic. On the contrary, experience has fully convinced me, that in no form of disease, not in any other stage of the venereal disease, is it proper to consider mercury in the medicinal quality, and for the prophylactic length of time, which causes, insurance, and prejudice used to sanction to form, days. Violent satisfaction, in all events, ought to be kept in check.

When I was an attached student at St. Bartholomew's Hospital, most of the venereal patients in that establishment were seen with their abundant complexions hanging round their mouths, their faces profusely spotted; and their voices flowing out in streams. The words were not sufficiently audible, and the speech was so gross that the place was almost the appellation of hell. Yes, notwithstanding mercury was then pushed for the venereal expression, it was then common to see many patients with the most dreadful eruptions, in consequence of the mercury of the penis; every individual, whose nose and palate were hot, and others who were afflicted with nodes and abscessed lymphatic nodes.

Happily, at the present day, the attachment to violent eruptions no longer prevails; simple excoriations and eruptions of the face are actively dissipated; and, even in what are reported to be true syphilitic eruptions, mercury is seldom given, except in very moderate doses, or such quantities as only gently affect the skin and salivary glands. The mercury now no longer blended with the constant use of the rapid and furious progress of syphilis when not duly treated by mercury, is now the very chief of practice which was itself the cause of all the aggravated forms of the disease. The consequence is, that our bad treatment of the venereal of two years ago is now hardly ever observed, except from the neglect and intolerance of patients themselves; and the few aggravated cases which are now seen, even in hospitals, are generally in that state previously to their admission. Another benefit also resulting from modern investigations, which prove that chancre, and all other varieties of the venereal disease, do not absolutely require mercury for their cure, is the safety with which it is now known that the use of such medicine may be postponed, when the patient's present state of health would not well bear its exhibition. And I know that an ignorance of this fact formerly caused the death of many patients.

The greater recent influence of syphilitic disease in England, I ascribe chiefly to the same judicious treatment now adopted, and not to any change or modification in the nature of the disorder. There are others, however, who may think that Mr. Ferguson does with regard to syphilis in Europe, that the disease has advanced a great deal of its virulence since long continued among us. But before we are altogether justified in drawing such a conclusion, we must first of all the bad practice which prevailed in former days, and which, in my opinion, is sufficient to account for the more severe forms to which syphilis then presented itself, though not for the progress of that acute, quickly spreading, and fatal disorder which broke out in the French army in Naples, at the close of the 18th century. According to my own judgment, this may be directly a very different disease from any venereal diseases with which we are now acquainted; for different indeed to be accounted for either by any spontaneous alteration of its own, or by any improvements in practice.

According to Mr. Ross's ideas, the most simple method of treating a chancre is to cauterize it with

caustic or the knife, whereas it is confined to the site of a venereal sore or ulcers, and breaks up as usual. However, he sometimes finds pus only on the first appearance of the chancre, when the surrounding parts are not yet contaminated; for he says it is absolutely necessary to remove the whole of the diseased part, and this object is exceedingly difficult to accomplish when the disease has spread considerably. When the chancre is situated on the glans penis, he thought treating the sore with the lunar caustic preferable to cutting it away, because the inconvenience from the illness this would be considerable when the cure of the chancre.

The caustic should be poured at the end, like a pencil, in order that it may only touch such parts as are really diseased; and its application should be repeated all the surface of the sore, after the separation of the last sloughs, until a red and healthy appearance, when it will heal like any other sore made with caustic.

When the sore is on the prepuce, or the coronal skin of the penis, and is in an incipient state, the same practice may be adopted with success. When the chancre is large, however, it cannot be destroyed with the aqueous solution, which does not cut up the increasing and deeply jagged. In such cases, Mr. Hunter thought that the patient must either amputate himself. When the caustic could not be conveniently employed, the author sometimes recommended the excision of the chancre, a plan which he had adopted himself, and the part afterward healed with caustic solution. However, says he, as our knowledge of the extent of the disease is not always correct, and as this inequality increases with the size of the chancre, the cure must be in some measure prevented by proper dressings, and it will be possible to drive the sore with mercurial ointment. When a chancre is destroyed almost immediately on its first appearance, Mr. Hunter believes that there is little danger of the constitution being affected, as it is reasonable to suppose that those has not been time for absorption to take place. However, on account of the impossibility of being certain on this point, he recommends mercury to be given from motives of prudence, the quantity of which medicine, he says, should be proportioned to the duration and progress of the sore. When the chancre is large, Mr. Hunter deems mercury absolutely necessary; and he observes that very little good is to be done by the excision.

Among modern advocates for the application of mercurial ointments, Dr. Keach is one of the most ardent, and the spirit of mercury is that which he excessively employs; for he obtains from this practice, however, what much edification is present.—(See, Clinique, 1.)

With respect to dressings for chancres, Mr. Hunter seems to have placed a good deal of confidence in those which contain mercury; but I do not believe that the same attention to them, perhaps now which existed twenty years ago. And the established use of mercury too being absolutely necessary is only was for the cure of different venereal sores, must have the effect of removing some prejudice on this part of the subject. As medicine is considered absolutely necessary in few cases, I have found it in many such a bad kind of dressing, and now seldom apply it to diseased surfaces. In ordinary cases, I believe mercurial ointment, made with the sulphur of sulfur, acetate of lead, &c. answer the best. Some chancres are indolent and require stimulants, like the hydragryne, arsenical, or bluish resin ointment, the arsenical hydragryne being some or less weakened, as a stimulant if the chancre is slow. Mr. Hunter, always partial, even to cases of indolent chancres, to mercurial dressings, expresses his preference to a more stimulating ointment, he believes more active than common mercurial ointment. In phagedenic and sloughing chancres, the issues and fomenting poultices, solutions of the extracts of leeches and opium; but particularly leech and water poultices with opium, and lotions of the extract of guaiacum, resins, or tincture of iron, and extract of olive, will heal.

In general, Mr. Hunter was an advocate for charging the dressings very often, because the acids excrete from the surface of the sore, as he is to diminish their effect. He states, that charging the application once a day will not be found to be effect, particularly when they are in the form of an ointment.

When the venereal nature of a chancre is removed,

the sore frequently becomes stationary; however, Mr. Hunter observes, that new discharges may be expected, and the quantity of ointment to be put to be increased. When chancres are indolent, Mr. Hunter says, they may often be cured by making them slightly with the lunar caustic.

In most cases, no treatment being possible in constitutional system, or the new skin eruptions on that surface, less effect has been observed to place. When sores are situated near the prepuce, when they are concealed by a phymosis, such lesions as greatly enlarged lesion should frequently be made under the foreskin, as is known to say some that might otherwise lodge there, and cause constant irritation.

Contrary to the doctrine which the force of some experience have now fully established, Mr. Hunter believed that mercury should be given in every case of chancre, however slight, and even when it has been destroyed by caustic, or other means, as he testifies experience. The reason, he says, should be to remove for some time after the chancre has healed, in order to render the venereal disposition from forming. But we find even Hunter himself falling into some contradictions; for, in other parts of his work, he makes a professed of the principle of giving mercury only in actual and visible disease exists, because it increases the disposition to it even if it fails. And as the chancre is cured, no further attempt of the cure from it is possible; and whatever tendency to the disease has arisen from absorption has long already been formed, and therefore cannot be prevented, and though, according to Mr. Hunter's own theory, in which has been long ascertained from the experience together with some of the eruptions, mercury is recommended with the view of preventing its return.

However, if Mr. Hunter's observation was to be taken as satisfactory on this part of the subject, I believe the fault is in his theory; for when a chancre has been destroyed, absorption, general disposition to the disease, and the practice of continuing to give mercury after the chancre is perfectly healed. To give mercury to this rule, present doctrine, in its absolute it is large and very long in being, as the chancre is generally cured a good while before the constitution is completely, and proceeding to the cure, under these circumstances, would be but a slow and a dangerous position.

Here, in a generalization, the case of the venereal instances of the venereal disease, as Mr. Hunter is obliged to; and which is some steps to be more constant than syphilis itself.—(See, *Essays on the Venereal Disease, and Nature of the Venereal Disease, by Thomas Sydenham, Esq. M.D. 1752.*) This part of the subject is treated by Mr. Hunter, who states that, in very complicated cases, it is not always necessary to continue when the effects of internal administration of mercury is to be continued; for the selected action is not so much stopped in a large chancre as it is in a small one, every part of the sore is equally exposed to the action, and of course cured with equal expedition. In an regard to elimination, direct excretion of urine becomes a large work is large; that is, the urine is being covered with skin. Hence, according to Mr. Hunter, a large chancre may be deprived of its urea, and within long before it has healed, when, as is either said, a small one may heal before the urine secretion has been destroyed. To be better in a representation of these points, both in general of the chancre and constitution, to consider the mercurial mercury a little while after the cure of chancre, as I have already stated, is a variation from certain parts of his own theory, however, with which it may be by experience.

As Mr. Hunter has explained, chancres, both in men and women, often acquire during the duration of the disposition, which are of various kinds, some forming the pimple and leaving the parts in an indolent state after the cure is accomplished. In some instances, a new disposition arises, which tends to cause the parts from healing, and often produces a small venereal disease that that from which it is derived. Such new disposition may lead to the formation of tumors. They are more frequent in the female than in the male, and generally occur only after the chancre has been healed from some peculiarity of the part.

constitution. They have sometimes been considered as cancerous.

Answering the question, Mr. Hunter notices those contained and other increased inflammations, suppurations, and abscesses, which issues diffused through the whole system, and also along the course of the glands, which become of a purple hue, attended with such a general thickening of the cellular membrane as makes the whole system appear considerably enlarged. The more violent these, and the obstruction in the vessels of the prostate with sometimes leucorrhoea, and sometimes in the body of the penis, and sometimes in different places of the whole, is indicated by a number of rapid scars. The glands often assume the same form, all more or less of it good. Frequently, the disease in this situation is probably destroyed by absorption, and the same is dissipated more they farther back. The ulceration, if unhealed, at length destroyed the parts. In the same case, prompt relief is demanded, but often the proper mode of treatment cannot be at once determined, owing to its ignorance with respect to the exact nature of the particular cause of the disease. Mr. Hunter states, that the destruction of the prostate is often of service when given in large quantities, and that the extent of leucorrhoea and hematuria are sometimes capable of effecting a cure. According to my own experience, the extension of abscess at first the constitutional point.

Sometimes, after a chancre has healed, the cicatrix breaks out again, and falls on the appearance of the preceding sore. Occasionally similar diseases break out in different places from that of the chancre. Mr. Hunter believes that they arise from a chancre in general, not epidemic, so fast, but, so far, is not being so painful, but as it is not attended, in not having such hard bases as venereal sores have, and in not producing leucorrhoea. This white is of a species that they are not venereal, and he states that they are very apt to recur.

Mr. Hunter does not specify any particular mode of cure for all these cases, but he mentions one instance which seemed to be cured by giving forty drops of the liquor potius, every evening and morning, in a glass of wine, and he alludes to another case, which was particularly cured by sea-bathing.

In some instances, after a chancre has healed, the parts, as Mr. Hunter remarks, do not alter, but appear to become thickened and indurated. Both the glands and prepuce are enlarged, so as to form in the end of the penis a tumour of considerable shape very much like a cauliflower, and, when cut away, showing red tissue from its base or origin towards the external surface. It is extremely indurated, and sometimes a consequence of the venereal disease; but Mr. Hunter has seen it arise spontaneously.

No medicine seems to be at all likely to cure the disease; the only successful means is to excise a considerable part of the penis, and then to keep a proper catheter introduced in the urethra.

Another disposition, induced by the prepuce, or prepuce of the chancre, is that to inflammation, or venereal tumour, called cancer. These are frequently considered, commonly as a consequence of the venereal poison, but as possessed of its specific disposition; and therefore, says Mr. Hunter, it is necessary to remove the cause of the disease, and it is said that with frequent other remedies then. This venereal prepuce, or cancer, may be removed by the effect, although the medicine was given in sufficient quantity to cure venereal diseases and a few venereal in the same person. (See *Went*.)

Mr. Hunter takes notice of a single thick cancer in the testicle from the effect of mercury on the system, and are apt to be mistaken for venereal cancer. He also mentions, that sometimes when the surgical treatment has been tried and been nearly failed, he has seen some persons break out on the prepuce near the first, and likewise on the appearance of chancre.

When, in the treatment of chancre, a skin arises, which the constitution is under the influence of a sufficient quantity of mercury to cure such cases, which medicine has also been called into the lower extremities on the same side as the chancre. Mr. Hunter supposes that the swelling in the groin is not venereal, but is produced by the mercury. In these cases, he always preferred purgative activity into the system in some other manner.

With respect to the treatment of chancre in women,

since it is difficult to keep dressings on the parts, Mr. Hunter advises the sores to be frequently washed with some mercurial solution, and applied with some such preparation of mercury as being perhaps the best, since it will act as a specific, and stimulant also when this is required. When the chancre, however, is venereal, they are to be treated in the same manner as venereal eruptions in men. When the sores extend into the vagina, this passage must be kept free from being constricted or closed, by the introduction of a tampon.

Sometimes, after a chancre and all venereal diseases are cured, the prepuce continues thickened and enlarged, so that the gland cannot be uncovered, perhaps owing to its being inflamed severely. Mr. Hunter, however, says, people sometimes try every possible means, and he informs us, that the steam of warm water, leeches, cauterizations, and caustic fumes, are frequently of service in such cases.

When the swelling and enlargement of the prepuce cannot be removed by applications, all the prepuce anterior to the gland point may be cut away. (See *Went*.)

Rule.—The immediate compression of a chancre, which is called a bubble, and almost always effects a cure by the constitutional or necessary symptoms, arising from the absorption of venereal matter from some surface where a chancre has been applied to.

We are already aware that Mr. Hunter believed the matter of chancre to be capable of communicating the venereal disease. Hence he explains in the following terms, the three ways in which he thought a bubble might arise in consequence of absorption. He observed, that the first and most simple manner is when the matter, either of a chancre or chancre, and only been applied in some single method, perhaps having produced any local effect on the part, but has been absorbed immediately after its application. Mr. Hunter observes, that he has seen instances of this kind, though he confesses that they are very rare, and that in most cases, necessarily of the same nature, a small chancre may be said to have existed.

The second mode of absorption, or that taking place in a chancre, Mr. Hunter supposes to arise frequently. That secondary symptoms do occasionally follow chancre is now commonly admitted, though whether they arise constantly from those which follow true chancre, is a point not yet completely settled. Delpech describes them as of the same nature (*Chir. Clinique*, p. 11), and his faculty of belief in the actual effect of syphilis and chancre is almost unbounded. On a point of this kind, therefore, I should not much much improve in his opinion. However, as far as Mr. Camille's experience goes, there is a difference, a part of which consists in the eruption being of the papular kind, and in the history being instances of simple primary chancre. (See *Chir. on the Symptoms*, &c. of Venereal Diseases, &c. *Lond* 1815.)

The third mode is the absorption of matter from an ulcer, which may either be a chancre or a bubble. This mode is by far the most common, and it proceeds, with many other circumstances, that it may be said to be the most favourable by absorption. Mr. Hunter believed, that absorption was rather apt to take place from sores on the prepuce, than those on the glands.

A fourth mode of absorption is from a wound; a case which, according to Delpech, is almost constantly followed by an eruption on the face, soon extending all over the body, and very quickly followed by swellings, eruptions, and pains in the bones. In short, his idea is, that when the poison is absorbed from a wound, especially one that has not suppured, its operation is peculiarly rapid and violent. (*Chir. Clinique*, c. 1, p. 254.)

Mr. Hunter states, that what is now commonly understood by a bubble is a swelling taking place in the absorbing system, especially in the glands, and arising from the absorption of some poison, or other irritating matter. When such swellings take place in the groin, they are called buboes, whether they proceed from absorption or not.

Mr. Hunter regards every abscess in the absorbing system as a bubble, whether in the vessels or the glands, when it originates from the absorption of venereal matter.

The matter is taken up by the absorbent system, and is conveyed by them into the circulation. In its passage through these vessels it often affects them with

both of the round ligaments; and the labium are affected in these ligaments, just before they enter the vulva. Mr. Hunter supposed each labium not to be pendulous, but only inflated alternately.

When the disease has attained the back, near or on the perineum, the abscess under is situated low side along the angle between the labium and the thigh, to the glands in the groin, and often, in this manner, small abscesses are formed in the sheath, near in these abscesses which occur on the penis in men.

When the effects of the poison do not end here, a lesion in the groin may be produced in the same manner as in men.

Owing to the difficulty of being sure that mercury and quinine have been taken, in other cases difficult to decide in cases that it seems to be a better remedy than of mercury. In men who have had no local treatment, the labium may only be removed when about absorption from the surface of the skin has taken place.

A labium, says Mr. Hunter, commonly begins with a sense of pain, which leads the patient to examine the part, where a small hard tumour is to be felt. This tumour lives every other inflammation that has a tendency to suppuration, and when absorbed, just as usual, and afterwards returns, the matter making its way to the skin very fast.

The above collected writer remarks, however, that some cases are more in progress. This circumstance he attributes either to the inflammatory process being kept back by mercury or other cause, or to its being confined by a scrophulous tendency.

The inflammation, he says, is at first confined to the gland, which may be marked when in the cellular membrane, but when the part has enlarged, or when the inflammation and suppuration are more advanced, the surrounding parts become more inflamed, and the tumour is more diffused. Some labia become complicated with an erysipelas, and infectious affections, by which they are rendered more diffused and less disposed to suppurate.

Mr. Hunter shows, due to distinguish very certainly the three venereal labia, from other swellings of the glands in the groin may be very difficult. He represents the true venereal labia, in consequence of a chancre, as being more commonly confined to one gland. It preserves the specific character of suppurative inflammation, and the results are different. It is rapid in its progress from inflammation to suppuration and abscess. The suppuration is commonly large, extending the size of the gland, and there is only one abscess. The pain is very acute, and the inflamed part of the skin is of a florid red colour.

Mr. Hunter describes very labia as arising without any visible cause, or being of two kinds. One soft labium and suppurative labium. These he always supposed to be venereal, although he admits there was no proof of it, and only a presumption deduced from the quick progress of the disease.

The second kind he properly preceded and attended with slight fever on the common symptoms of a cold, and they are, for the most part, labia and does in their progress. If they are earlier than mercury, they become more diffused than venereal labia, and they are often confined to one gland. When very large, they give but little sensation, but when smaller, the sensation is more acute, almost all at once as in venereal cases. They usually do not suppurate, and often become indurated. When they do suppurate, it is not a slow swelling, but suddenly it is more glands than one, while the inflammation is more diffused and not accompanied by tenderness to the swelling. The matter within is thick to the skin, and the part affected is of a more purplish red. Sometimes the abscesses are very large, and are painful.

In considering whether the condition of the inguinal glands are of any use without the first thing to be attended to is, whether or not there are any venereal symptoms. In these two cases, Mr. Hunter observes, that there is a strong presumption that the swelling is not venereal. When the swelling is only in one gland, very slow in its progress, and gives but little or no pain, it is probably merely scrophulous. However, when the swelling is considerable, diffused, and attended with more inflammation than pain, the inflammation is most probably affected with slight fever, the symptoms of which are headache, loss of appetite, want of sleep, weak quick pulse, and an appearance

of approaching fever. Such swellings are long in getting well, and the disease is to be affected by mercury, even when venereally applied.

Mr. Hunter mentions the having seen the above affection of the groin, together with the constitutional disposition, take place where there were no symptoms; and he was puzzled to determine whether the disease in the groin was symptomatic (secondary) of the constitutional, or whether it arose from the absorption of mercury. He had long suspected that there was a third case, and was at last, certain that such a case might prevail. He had seen instances, in which the venereal matter, like a cold or fever, only inflamed the glands in the groin, producing in them abscesses, in which they were absorbed.

In such cases, says Mr. Hunter, the swellings commonly grow slowly, give but little pain, and if mercury be given to destroy the venereal disposition, the progress is accelerated. Some suppuration usually under this swelling occurs; and others, which probably had a general taint at first, become so incident, that mercury has no effect upon them, and, at the end, they either get well of themselves or by other means.

According to Mr. Hunter, labia are local complaints. When a labium is judged to be venereal, and only in an inflamed state, an attempt is to be made to induce the swelling. The property of the attending mercury, depends on the progress which the disease has made. If the labium be very large, and suppuration appears to be near at hand, resolution is not likely to be effected. When suppuration has already taken place, Mr. Hunter says he decided the probability of any success attending the resolution, which now may only retard the suppuration and protract the cure.

The treatment of these inflammations, says Mr. Hunter, depends principally on mercury, and almost exclusively on the quantity which can be made to pass through the skin. When suppuration has taken place, the cure also depends on the same circumstances. Hence, he recommends the mercury to be applied to such surfaces as allow the remedy, which should be passed through the diseased gland. In this matter he coincides that the disease in the groin might be withheld, and that the constitution would be less likely to be compromised. At the same time, he admitted that the quantity of mercury taken is such, as not to have much surface for absorption beyond these; for instance, the labium on the body of the penis, or even from the skin on the garter strap. This principle has been much insisted upon by Despatch in his late work—(Chir. Chirurg. 7, 1, p. 302.)

As venereal labia are, in effect, a consequence of abscesses or venereal sores, and glandular swellings in the groin may take place from other kinds of sores or local irritations, and even from various constitutional causes, while modern surgeons profess their incapacity always to pronounce the character either of a primary sore or a labium by its first appearance and progress, it is evident that the same difficulties present themselves here as in cases of primary sores, respecting the principles by which the treatment should be guided. It is likewise to be remembered, that labia, when supposed to be decidedly syphilitic, are not, as Mr. Hunter himself, absolutely intolerant without mercury. The first tendency, also, which Mr. Hunter had, and Despatch has, is the doctrine of the benefit derived from the practice of rubbing mercury into surfaces from which it would be conveyed directly to the diseased glands in so high to remove the swelling and promote the resolution, in case now regarded as an unpropitious subject. As Mr. Hunter has judiciously remarked, there is some inconsistency in Mr. Hunter's own statements upon this point. He is one place he admits, that mercury, applied in the best and right for the cure of a chancre, will sometimes cause, instead of dissolving a labium—(P. 304.) And Mr. Bacon observes himself, that mercury so frequently promotes the suppurative of labia as their disposition—(Ibid. Syphilis, p. 341.) And reporting the practice of using to make the mercury pass through the diseased glands, Mr. Hunter never contradicts himself in another place, where he confesses his own doubts of its utility in suppurative labia. However, he admits that mercury alone is not always capable of effecting the cure of such labia as are deemed venereal; and when the inflammation runs very high, he approves of bleeding, purging, and emetics. When the inflammation is

Local Effects.—Surgens truly, that a local venereal has taken place, when the venereal virus has been absorbed into the circulation. Mr. Hunter does not think the epistemic constitutional activity proper in its application to this form of the venereal disease. By constitutional disease, he means, he should understand that in which every part of the body is acting in one way, as in fevers of all kinds; but the venereal poison seems to be only diffused through the circulating fluids, and, as it were, as from remote parts of the body to excite the venereal action, which action is perfectly local. To use Mr. Hunter's phrase, it takes place in different parts in a regular succession of constitutionalities. Only a few parts are acting at the same time; and a person may be constitutionally affected in this way, and yet almost every function may be perfect.

The venereal poison is perfectly conveyed into the system from a phlogon. It may also introduce to Mr. Hunter's doctrine, he observed that a person who has been taken a possibility of its getting into their system from the surface of the body, without any previous constitutionalities. According to his doctrine, it may be admitted from common sense, without necessarily embracing this opinion; and it may be taken up from wounds, in which cases it quickly first excites attention.

General Effects.—In consequence of the blood being contaminated with real venereal pox, it might be supposed that the local effects thus produced would be similar to those caused by those producing them. Mr. Hunter believed that this is not the case. He notices, that the local effects from a constitutional contamination are all of one kind, viz. ulcers, but the effects make their appearance on any surface whatever, rather the result of common sense. But Mr. Hunter observed, that at the same time, in the constitutional, when it acts upon the same specific principles as that which is externally applied, a common sense would arise when it affects a canal, and only some of characters which it attacked other surfaces.

Mr. Hunter found, that even the sores which are caused in the same are very different from each other. He says that the venereal pox produces considerable inflammation, often attended with a great deal of pain, and quickly followed by suppuration. On the local effects arising from the virus in the constitution, are slow in their progress, attended with little inflammation, and are seldom or never painful, except in particular parts. However, Mr. Hunter allows that the singleness in the effects of the pox, depends on the nature of the parts diseased; and he says, that when the throat, nose, or eye are affected, the progress of the venereal infection is rapid, and leaves a greater resemblance to a chancre than when it occurs on the skin. Even in these parts, Mr. Hunter thought, that the effects were attended with less inflammation than those which were spreading in general order.

Before the time of Mr. Hunter, the virus seemed by sores which arise from a constitutional infection, was always considered to be of a poisonous quality, like the matter of a chancre. At first, one would expect that this must actually be the case, because venereal sores occur in the same, and usually pass through the same stages proceeding from a hard venereal. Mr. Hunter remarks, however, that the latter circumstance is from a local pox, since mercury is capable of curing many diseases besides the venereal. He also takes notice, that when pus is absorbed from a chancre, it generally produces a chancre; but that a chancre is never produced by the absorption of matter from a venereal sore arising from the virus diffused in the circulation. For instance, when there is a venereal ulcer in the throat, no bubo occurs in the glands of the neck; when there are syphilitic sores on the arm, by even separating matter in an abscess, no swelling forms in the glands of the axilla, although these compounds occur when fresh venereal matter is applied to a common sore on the arm, hand, or leg. No swelling or profusion in the great or superficial nodes, or buboes on the inguinal glands.

These very important experiments are related in Mr. Hunter's Treatise on the Venereal Disease, in order to prove that the matter from a chancre, or chancre, is capable of affecting a man locally, when it is already suffering under a local venereal, and that the matter from secondary syphilitic sores has not the same power. The particulars, however, are too long to be inserted in this book.

Parts most susceptible of the Syphilitic Venereal.—Some parts of the body seem to be much less susceptible of the venereal virus than others. Indeed, Mr. Hunter observes, that, as far as our knowledge extends, certain parts cannot be affected at all. The brain, heart, stomach, liver, kidneys, and several other viscera, have never been known to be attacked by syphilis.

The first order of parts, or those which become affected in the early stage of the venereal, are, the skin, mouth, nose, throat, inside of the mouth, and sometimes the tongue.

The second order of parts, or those which are affected at a later period, are, the pelvis, testis, penis, and bones. Mr. Hunter conceived, that the great reason for the superficial parts of the body suffering the effects of the venereal poison, was the deep-seated nodes. Depending on the fact, being more exposed to external cold. He remarked, that even the second order of parts, not all were so situated in the same way, nor every where at once. For, on the contrary, which are the external surface of the body are first diseased, as, for instance, the pectorals, bones of the back, the face, arms, bones of the nose, &c. Next, the disease affects those bones equally on all sides; but first on one side which is next to the external surface. It was Mr. Hunter's belief, however, that the susceptibility of particular bones did not altogether depend upon their position in the skin; but upon the circumference and their hardness or softness.

The following account by his name agrees with the results of modern inquiries into the nature of the venereal disease; as follows may be given, it is possible that the bones are very seldom affected by it. Thus, on the venereal nodes were traced by Mr. Rose without success, he observes, that "the constitutional symptoms were evidently not such as could be regarded as venereal, if the virus could be so generally received into the system. Cancer of the bones, and some of the least venereal symptoms, did not occur. In an instance, therefore, that had first process, with secondary pty, from one order of symptoms and parts almost in another, which is considered as an essential characteristic of the venereal disease." (Edin. Med. & S. p. 425.) We have also from Mr. Gulliver, that the bones were not affected in any of the cases noted during his stay in the York Hospital, though there were several other cases admitted. "In which a few venereal nodes had been taken, but the venereal infection, and in which secondary symptoms were followed by eruptions, both regular and venereal, by ulcers in the throat, &c. &c. and in one case, by inflammation of the pectorals covering the bones, and enlargement of the spleen, and, although mercury was resorted to for its cure." (Edin. Med. & S. p. 565.) The late Dr. Patrick McGehee, however, recorded one of two or three cases, in which a node was taken, although mercury had been used. The occurrence, in all events, seems to be rare.

In the examples from which Mr. Hunter, under the supervision of Dr. Hennen, was professor did not see "a single case in which the decay of the bone was attended with some cases of pty, and of pain and swelling of the bones of the cranium and extremities, were met with; but, except in two, he never remarked any nodes which could be regarded as venereal or syphilitic." One of these yielded to blisters and antisyphilitic; the other, after resolving granules and abscesses, was dispersed by mercury. (Edin. Med. & S. p. 561.) Dr. Hennen's statement on this subject would have been very satisfactory, had it comprised his opinion of the characters of the venereal nodes. On the whole, it appears extremely certain that mercury, especially when employed inunctionally, and even when resorted to in solution, and the patient exposed himself to a long and cold, tends to promote the frequency of nodes, as a sign of the venereal disease; though as the last has abundant proof of the same, it is not necessary to state the same consequence after other complaints, and venereal ulcers, throat ulcers, &c. as an evidence, rarely lead to nodes; it might even be that these nodes were the product of the condensed action of syphilis and mercury together. The infrequency of nodes in the most non-venereal pty, is one of the most important facts not established in its history, and it is curious to find, from some quotations made by Dr. Hennen, that it was well known to French physicians. Fallopius, in his 20th chap. De Quatuor Corruptionibus, speaking of the

the military hospitals. To some facts relating to this question I have already alluded.

There is no little certainty about the essential characters of syphilitic eruptions, so that the test of every other symptom of the venereal disease is rather dubious. When Mr. Hunter considers the eruption as peculiarly occurring over the whole body, Dr. Broussais states, that syphilitic eruptions of the skin commonly make their first appearance on the face, where they are usually copious, and on the hands and wrists.—(Précis. Sympt. de Catarrhes Vénériens, p. 204, et. 1.) Their colour, he says, is in general less livid than that of contagious eruptions, being of a brownish-red or different shades; but that this is not universal, the same of the syphilitic erythema have a bright and hard in the beginning. Eruptions he said degenerate their progress into various modifications; while, on the other hand, various periods and exacerbations them.—(P. 205.) According to Hunter, the desquamation ceases the skin appears settled, and many of the syphilitic disappear, while others continue and increase with the disease.

In other cases, the eruption returns for a distinct period, which are often not observed till the skin has begun to firm. At other times, the eruption assumes the appearance of small distinct inflammations, constituting nodules and receiving various red tints, however, as pyramidal not acted on the tissue. Mr. Hunter also observes, that venereal blotches, on their first coming out, are often succeeded with induration, which gives them a degree of transparency which is generally greater in the sterner than the wrist, especially if the patient be kept warm. In a little time, the induration disappears, and the nodules peel off in the form of a scurf. The latter sometimes often, outside the patient and the surgeon, who look upon this as a sign of the inflammation as a sign of the disease, till a succession of such undecaying ones.

The parts affected next begin to form a copper-coloured, dry, lenticular crust, called a scurf or scab. This is thicker of old and new cases are formed, which spread to the breadth of a finger or shilling; but seldom more extensively, at least for a considerable time. In the newer ones, every succeeding scale becomes thicker and thicker till it has a brownish, somewhat scale. Then the disposition for the formation of the same kind place in the same gradually, and a new skin is produced, which commonly spreads, although in a short way.

When the affected part of the skin is exposed by another portion of skin, which keeps it in some degree moist, as between the nates, about the wrist, between the forearm and the thigh, in the angle between the two thighs, or the red part of the lip, or in the armpits, the eruptions, instead of being attended with scurf and scale, are accompanied with an elevation of the skin, which is covered with characteristic lymph into a white, soft, moist, flat surface, which discharges a white matter.—(Hunter.)

Dr. Anthony Cullen has pointed out what he terms as hepatic eruptions of the cuticle on the breast or abdomen, having the appearance of several blotches. Because that it is less deep in the skin; that it has only an inflammatory tone; and that it is not so deeply penetrated, as the true venereal blotch. It never forms a passing point; but is simply a fading, some scaling of the cuticle. This form of disease seems to him to be produced by a disordered stomach and liver.—(See Lect. Med. Jur. et. 7, p. 98.)

A venereal eruption often attacks about part of the finger in which the nail is formed. Here the disease involves the entire nail, which is soon falling through the nail, and if allowed to continue, a separation of the nail takes place.

When either part of the body covered with hair is attacked, the hair separates, and cannot be reproduced as long as the disease lasts.

Mr. Wilsont describes the true syphilitic eruption, as consisting of firm and slightly elevated spots, from which polices or scales are free, and prominent, sometimes detached. These spots are thick about the scalp, chin, forehead, and upper and lower part of the thighs. When these break, they commonly form slightly elevated crusts of a pale colour. On the palms of the hands, or sides of the feet, they are characterized by a thick honeycomb disposition of the same crusts. They are more disposed to superficial ulceration, when confluent, or in small degrees exposed

and meeting surfaces, as the angles of the mouth, axilla, and thigh, &c.—(See Med. Cur. Trans. vol. 13, p. 561.)

It must be allowed, that it is frequently very difficult to say, whether an eruption is syphilitic or not, and an opinion should rather be formed from the history of the case than from any particular appearance of the eruption itself. As Dr. Broussais has remarked, the venereal eruptions, which are the result of the venereal poison, are often misinterpreted, and considerable embarrassment to the practitioner. They assume such a variety of forms, that they defy definition by any arrangement founded upon their external character; and, in fact, they progress to various or exclusive states, by which their nature and origin are lost. Thus, in some, we see a series of catarrhal appearances, and scarcely any trace of species of the venereal eruption, which these secondary eruptions of syphilis do not occasionally resemble. Dr. Broussais admits, however, that, in every case, there is a difference, which a practiced eye will recognize, between the venereal diseases of the skin and the syphilitic eruptions, to which the other generic appellation might be given. This, says he, is often observable in the shade of colour, in the manner accepted by the eruption, in the mode of its distribution, and in the general complexion of the patient. Hence, to a person conversant with these ordinary diseases, a degree of accuracy in these respects will immediately excite a suspicion, which will lead him to investigate the history of the progress of such an eruption, and of its concomitant symptoms.—(See Broussais's Medical-Symptoms of Venereal Diseases, p. 211, 222, et. 2.)

Dr. Hunter does not pretend to be able to distinguish the true syphilitic eruptions from others, and, indeed, by what criterion they are to be known, and upon what point, as compared, with the observations factually established by recent experimental inquiries. Dr. Hunter generally approves of defining the use of punction at first, in order to see whether these eruptions affected will yield to other means; "but says he, I should not very long postpone the employment of the mild mercurial treatment, aided by warm bathing and sedatives."—(On Military Surgery, ed. 2, p. 388.)

Venereal Disease of the Throat, Neck, and Tongue.—In the throat, inside and outside of the mouth, the disease is said by Mr. Hunter generally to make its appearance at once in the form of an ulcer, without much previous inflammation. Consequently, the tonsils are not much enlarged.

A venereal ulcer in the throat was supposed, by the same author, to be, in general, tolerably well marked, though he observes, that it may not in every instance be distinguished from an ulcer of a different nature. Several diseases of the throat, he remarks, do not produce ulceration on the surface. One is extensive inflammation of the tonsils. The inflamed place often suppurates in the centre, so as to form an abscess, which bursts by a small opening; but never looks like an ulcer that has begun specifically, like a true venereal ulcer. The case is always attended with too much inflammation, pain, and enlargement of the parts to be venereal. Also, when it suppurates and bursts, it is visible directly, and it is generally attended with other inflammatory symptoms in the constitution.

Mr. Hunter then refers an ulcerated transfection of the inside of the throat in many persons, whose constitution is supposed to be syphilitic. The complaint progresses a thickness in the speech. Sometimes a papillary growth is thrown out on the surface of the palate affected, and various appearances attend, as by some called ulcers; by some, cancrs; and by others, gonorrhoic sore throat. The case is attended with too much swelling to be venereal, and, with a little care, it is easily to be distinguished from an ulcer or loss of substance. However, when this difference is not obvious at first sight, it is proper to endeavor to remove some of the lymph, and, if the surface of the mouth immediately should appear to be free from ulceration, we may conclude with certainty that the disease is not venereal. Mr. Hunter states, that he has seen a thick film with papillary growth, so as to appear very much like an ulcer; but, on removing the substance, the small artery beneath was found perfectly sound. He adds, that he has seen cases of a rounded mass having a thick in its centre, which slough, before its detachment, looked

very like a foul ulcer. The stage of the complaint, he says, is extremely puzzling when the abscess has come out, for then the discharges seem of the character of the venereal ulcer. Whereas he met with the disease in its first stage, sometimes treated as if it had been of the nature of syphilis, or a carbuncle. When the complaint is in its second stage, without any preceding local symptoms, he recommends the practitioner to suspend his judgment, and to wait a little, in order to see how the nature is able to relieve itself. If there should have been any preceding fever, the case is still doubtful as to be venereal. Mr. Hunter informs us, that he has seen a sore throat of this kind taken for a venereal case, and mercury given, until it affected the mouth, when the vesicles, located on a suppuration of all the parts concerned in the first disease.

Another complaint of these parts, which Mr. Hunter represents as being often taken for a venereal one, is an ulcerous excoriation, which sometimes affects the surface, becoming very broad and sometimes deep, having a regular termination, but, upon going deeply into the substance of the part, as Mr. Hunter believes the venereal ulcer does. No part of the inside of the lip is exempt from this ulcerous excoriation; but, according to Mr. Hunter, the disease most frequently occurs about the root of the tongue, and spreads forwards along the palatine arch. He remarks, that the complaint is evidently not venereal, since it does not yield to mercury. He believes these ulcerous excoriations continue for weeks, without exhibiting any change, and during several other make its appearance on the surface of the cross-bone joint. He says that such excoriations were cured by leeches, after the end of the venereal course, by which the syphilis was now cured.

This writer describes the true venereal ulcer in the lip, as a *fungus* of substance, part being dug out, as it were, from the body of the lip itself. It has a determinate edge, and is characteristically firm, having thick white matter, like a slough, adhering to it, and not resembling being washed away.

According to the experience of one late writer, the ulceration of the mouth is attended with little pain at first, and excavates the part deeply, and often is a triangular form, as if the lip were split. It slowly acquires a smooth white surface.—(Wellcock, in 35th Ann. Trans. vol. 12, p. 598.)

Here, however, as in most other suppurated forms of syphilis, some tend to healing, by which the case may be completely distinguished from other diseases of the throat presenting similar appearances: for, as Mr. Ross has very truly remarked, "the excavated ulcer of the tongue, as described by Mr. Hunter, is not, as Mr. Cruveilhier seems to think, a peculiar symptom of the progress of the syphilitic virus. I have repeatedly seen this well as the scaly blotch, in cases where mercury had been freely employed for the primary virus, and in which I considered the virus as eradicated, and which have disappeared under the use of antisyphilitics."—(Med. Cas. Trans. vol. 5, p. 221.) In a recent work, Mr. Cruveilhier himself acknowledges the justice of the preceding observations, and avers that when the ulceration of the tongue, he has often noticed the excavated ulcer of the lip, often attended by the binary palmaric ulcer, or the train of constitutional symptoms which arise from it.—(On the Symptoms, &c. of Venereal Disease, p. 37.) In affection of the throat, Dr. Hennen says, that he "would be more guarded than in any other in the employment of mercury, until an inflammatory disposition was removed." A patient he has with these glands, "as if by magic, as soon as the local effects of mercury on the parts within the mouth became obvious." But, when mercury was given orally, he has seen a real number of instances in which immediate relief was lost.—(On Military Surgery, vol. 2, p. 528.)

According to Hunter, the venereal sometimes produces a thickening and hardening of the tongue, but frequently ulcerates, as in other parts of the mouth. He describes venereal sores on the tongue as generally more painful than those on the skin; but less so than common venereal sores from ulcerated canals. They excite the patient to speak thick, as if the tongue were too large for his mouth, with a small degree of swelling. Mr. Hunter thought the relief of a venereal ophthalmia, but that one form of it arises from this cause, is in general a fact universally admitted. Another subject of this, in the same ophthalmia.

Symptoms of the second stage of Last Venereal.—The penicillium, herpes, herpes, ligaments, and being in the parts which Mr. Hunter sometimes so fully and affecting in the second stage of last venereal. These symptoms, in its full extent, however, appear to be ascribed rather questionably, as it would appear that the evidence both of vesicles and nodules seems that they are of venereal origin, of the kind, and being deeply carried, rarely take place from syphilis, and may carry to syphilis. It is an observation of Mr. Hunter's, that we cannot always know with certainty what parts may become affected in the course of the disease. He says he has known the vesicular produce a total deafness, sometimes followed by suppuration, and great pain in the ear and side of the head. These are fully explained, that it was one of the venereal's doctrine, that the second order of parts was generally deep-seated. When these "nodules" arrived at the point, he observes, that the progress of the disease is more gradual than in the first order of parts. It sometimes very much the character of venereal eruptions, or chronic inflammation; only it differs in the parts are frequently than the latter, afflicting also. A swelling sometimes involves the appearance of a hole, and there has been possible means of catching or poisoning for many months; and, in consequence of the little pain experienced, the patient may be in considerable ease before it is noticed. Sometimes a granular of parts is felt; but no swelling exists in the latter, as long as it is. According to Mr. Hunter, these nodules are also applicable to swellings of the tongue and lip. As numerous of this kind can become very dangerous, they are localised with syphilis, as such inflammation. When they attack the pharynx, they seem like an enlargement of the tongue, and in some cases of being very firm, and closely connected with the latter part. Mr. Hunter also notices that, in these advanced stages of the disease, the inflammation can hardly get beyond the pharynx, but is held up; it continues to become more and more, and often matter is formed if it is not removed, but a sharp dissection. Some, indeed, he says, are of the tedious and long, but for years, before they become matter in it. These cases he considers as being actually venereal, though commonly considered as such. Mr. Hunter found it difficult to explain this, why, when the venereal attacks the base of the pharynx, the pain should sometimes be insupportable, and sometimes very trivial. Venereal pain in the base are described by Mr. Hunter as being of a peculiar kind, peculiarly most severe in the night time.

At the present day, when many cases formerly supposed to be syphilitic are treated without any mercury, and even those which are reported to be treated by such by much smaller doses of that medicine as were given in Mr. Hunter's day, nodules have become much less frequent; and I have already, in a certain part of this article, expressed my decided belief in the progress of the opinion given by Felsing and some that a disposition to nodules is often removed by its attack of mercury.

Treatment of Last Venereal.—In Mr. Hunter's view, the first order of parts, or those which are not susceptible of being affected in this manner, as far as the most easy of cure; while the second order of parts takes more time to be removed.

In the case of complaint arising in the second order of the last venereal, Mr. Hunter believed that the tendency in condition the long-point of mercury till all the swelling had disappeared. For a is observed by this distinguished writer, that, even high local complaints cannot contravene the influence by mercurials, and have the internal disposition and action from the constitution can be treated with the local effects and means, and even even when in condition, keeping order on the local state, it has proceeded to suppuration, there can be no reason for continuing the course after the venereal virus has been destroyed. Whatever may be benefited by covering the immensity of mercury as it tends to many secondary symptoms, one thing seems which will do us no harm, that it should always be combined with mercurials, but it produces little effect, and more terrible diseases than those which it is intended to relieve. For an account of the various ways of exhibiting it, I must refer to the article *Mercurial*. Dr. Depaul adopts the notion, that the mercury brought

of the venereal disease are been successfully treated by irritating mercury into the system from the surface of the body, and, if possible, partly through the mucous set of absorbents as first took up the virus; for the rate of secondary suppuration he predicts the time and—(Clib. Cils. 1-2.)

To the following arguments concerning the operation of mercury, and the principle by which its administration should be regulated, surgeons of the present day will not give more credit than time warrants; because none of Mr. Hunter's opinions are justifiably influenced by the hypothesis that mercury is absolutely necessary for the cure of the venereal disease.

In curing the late venereal mercury can only have two modes of action, once on the poison, the other on the constitution. It says Mr. Hunter, mercury acted on the poison only, we might suppose, if it did so either by destroying its quantity, by decomposing it, or else by arresting it, and carrying it out of the circulation. If mercury acted in the first of these ways, one would expect that the cure would depend on the quantity of the mercury taken into the system. If it acted in the second manner, one would infer that the progress of the cure would be proportional to the quantity of excretion. For observes Mr. Hunter, if it act upon the principle of destroying the chemical action of the living parts, and of counteracting the venereal irritation by producing one of a different kind, then another quantity above our excretion will send much. He states, that the progress of the cure depends upon quantity joined with specific effects. However, it is sufficient to observe that the effects which mercury has upon the venereal disease, are in some degree proportional to the local effects of the medicine on some of the glands or particular parts of the body, as the mouth, skin, kidneys, and intestines, yet such effects are not altogether proportioned to those other circumstances. When mercury disagrees with the constitution, so as to produce great irritability and hectic symptoms, this action of irritation, as Mr. Hunter explains, is not a counter-indication to the venereal disease.

It was also noticed by the same author, that the effects of mercury when secreted are always in proportion to the quantity of the mercury excreted in a given time, and the susceptibility of the constitution to the secreted irritation. He says that these circumstances regulate the most salutary effects, and that, in order to obtain the greatest action of mercury upon salivary, and in the most efficient manner, the medicine must be given till it produces effects elsewhere. However, it must not be continued too quickly, in order that a sufficient quantity may be given before we are obliged to stop, in consequence of the effects. Mr. Hunter states that when the local effects are produced too quickly, they prevent a sufficient quantity of the remedy from being taken into the system to counteract the venereal irritation at large.

Mr. Hunter observes his having seen some cases in which mercury acted very readily locally, and yet the constitution was hardly affected by it, so the disease would not give way. He states that he has met with other cases, in which the same quantity of mercury did no answer, till it was given so quickly as to affect the constitution, so that it remains so to produce local irritation, and, consequently, salutary excretion. This, he observes, is a proof that the local effects of mercury are when the size of its specific effects on the constitution is large, and it shows that the susceptibility of the diseased parts to be affected by the medicine is in proportion to its effects on the system. Its effects, he concludes, are not to be judged of practically, but to its irritation. Hence he concludes that mercury should be given, if possible, in such a manner as to produce salutary effects upon some parts of the body, and in the largest quantity that can be given to produce these effects without fatal results. Mr. Hunter also remarks, that these salutary effects should be the guide of determining how far the specific may be pushed, so as to have the greatest effect on the disease without endangering the constitution. The practice must vary according to circumstances, and if the disease be in a slight degree, less mercury will be had to the constitution, and mercury will be thrown less on the system in large quantities; a very disagreeable mistake, as far as I can judge from many cases in which I have seen it acted upon.

Mr. Hunter observes again, that when the disease is in the first order of purity, a smaller quantity of mercury is necessary than when the second order of the poison is affected and the disease has been of long standing; its first appearances alone being cured, and the venereal disposition still remaining in the secondary state. For the purpose of curing the venereal disease, whether in the first of classes, lues, or late venerea, Mr. Hunter was of opinion that probably the same quantity of mercury is necessary. He supposes that one ounce of mercury at such quantity as the virus is the same person, and a small one as much as a large one. He thought that the only difference, if there is any, would depend upon the nature of the parts affected, that is, on their being entirely active or passive. He conceived, however, that, on the whole, recent venereal symptoms accordingly were difficult to cure than the symptoms of late venerea, and that this may be the difference in regard to the quantity of mercury necessary.

Having now delivered the principal general instructions relative to the exhibition of mercury in the treatment of the venereal disease, as given by Mr. Hunter, I must not quit this subject without remarking that even this eminent surgeon appears on the whole too partial to the long use of mercury, and sometimes to the introduction of immoderate quantities of it into the system. In practice, however, his observations tend to moderate all violent actions. It is to be considered that, in his days, lues had a reputation that truly epidemic; but this reputation is allowable, with the caveat he himself has distinguished by their appearance, would in the end spontaneously heal, and he himself had no dependence upon any medicine except mercury for the cure of the late venereal disease. But consider experience evinces that the disorder seldom more promptly itself to itself so had and intractable as formerly; that it is even capable of spontaneously curing; and that the tardy even cases in which it is requisite to give mercury, require a very moderate quantity. Indeed, such is the change, that many surgeons expect that the very nature of the disease must have undergone a material alteration or modification. In England, in my opinion, every thing is to be referred to the improved science of exhibiting mercury only in moderate doses, and never pushing to exhaustion till the constitution was required that is tolerable form of disease cure, which encompasses the compound effect of mercury and syphilis together; and, in other instances, of this description which experience frequently call applied to phlogoplastic, and depending upon the venereal poison at all, but upon a state of the system, which mercury is known to aggravate in the worst degree. For additional information concerning internal remedies for the venereal disease, see Mercury, Quinine, Mercury, Mercuric Acid, Nitric Acid, Sarsaparilla, Sulphuric Acid, &c.

With respect to the local treatment of the symptoms of late venerea, Mr. Hunter thought that some would in general be necessary, since the constitutional treatment would commonly effect a cure. However, he admits that sometimes the local effects will not give way, and the parts remain swollen in an indolent, but increased, even after there is every reason to believe that the constitution is perfectly cured. In such cases, he recommends assisting the constitutional treatment by local application of mercury to the part, either in the form of a plaster or ointment. The latter application, he says, is the best. When time is not sufficient, he attempts to attempt to be made to assist in the formation of mercurial lues. He says, he has seen a mercurial cure, which goes throbbing parts, and by itself having an injection down to the whole length of the veins. The pain ceased, the swelling decreased, and the cure lasted up kindly, without the assistance of a grain of mercury. He mentions that lues have been applied to some of the various, removing the pain and taking away the swelling.

With regard to these late cases, I may add that, for many years past, the use of constantly dispensing cases by mercury has been entirely abandoned by every of the best practitioners; and, in general, best instructed medical persons for the cure of such venereal cases are easily distinguished. When such moderate quantities of mercury have been then sufficient, a skin is applied over the swelling, and kept open; and

which give the tumour generally external, as far as its extent will allow.

Disease resembling the Venereal. *Prædisposition.*—Seen on the glans penis, prepuce, &c., in the skin of children, as Mr. Hunter says, may and do arise without any venereal infection; and sometimes they are a consequence of former venereal sores which have been cured.

The symptoms produced by the venereal poison in the constitution, are such as are common to many other diseases. For instance, Mr. Hunter remarks, that blotches on the skin are common to what is called a scrofulous habit; pains are common to rheumatism; swellings of the bones, periosteum, &c., are in many and various periods of the scrofulous and strumous kind. Thus, says he, most of the symptoms of the venereal disease, as all its forms, are to be found in many other diseases. Hence, the original cause, and many leading circumstances, such as date, effect, &c. of the disorder upon which, from occasion, when very local, the possible and probable symptoms, &c. must be considered, before an use is made, absolutely what the disease truly is. All the circumstances and symptoms taken together may be such as will afford no other disease. However, Mr. Hunter confesses that, with all our knowledge, and with all the application of that knowledge to suspicious symptoms of this disease, we are often mistaken, taking symptoms common which are not it, and sometimes appearing really syphilitic affections to be of another nature.

Mr. Hunter takes notice that, in some constitutions, rheumatism, in many of its symptoms, resembles the venereal. The nocturnal pains, swelling of the tendons, ligaments, and periosteum, and pains in loose articulations, are symptoms both of the rheumatism and also of the venereal disease, when it attacks such parts. Mr. Hunter, however, did not know that he had very early the first venereal attack the joints, though many rheumatic complaints of such parts are cured by mercury, and therefore supposed to be venereal.

Mercury, given without caution, often produces the same symptoms as rheumatism. Such complaints Mr. Hunter has used mistaken for venereal ones, and mercury continued. He explains that some diseases not only resemble the venereal in appearance, but in the mode of continuation, proving themselves to be poisons by affecting the part of excretion: thus producing immediate consequences similar to buboes; and some remote consequences similar to the liver disease.

Mr. Hunter observes, that it is nearly as dangerous to give constitutions to give mercury when the disease is not venereal, as to omit it in other cases which are really syphilitic; and, had he been acquainted with recent investigations, he would undoubtedly have gone further, and decided that it is in reality far more dangerous. Many of the constitutions which put on some of the venereal symptoms when the disease is not really present, he says, are those with which naturally scrofulous system, and especially the lues. He had seen mercury which was exhibited for a supposed venereal ulcer of the thistle, produce a mortification of those glands, and the patient was totally destroyed. No doubt this was an example of what Mr. Cammack would call the phlegmatic venereal disease.

Mr. Abernethy, in his *Surgical Observations*, 1804, has traced at some length of diseases resembling syphilis, and has added several very interesting cases, which I believe every student practising to read with the greatest attention, as they contain the views of the subject fully established.

"A patient says he thought that he had received a slight cut on the hand (which was extended to the first and middle fingers) with the discharge from a hole in the finger, that he had begun to recover. The wound healed after it was about the size of a sixpence, which he supposed was, and which I affirmed had not the thick red edge and hard, and other characters of a venereal chancre. I therefore recommended him to try the effect of local issues, and not to use mercury."

In about a month, the sore, which had opened with the disease described in its appearance, and assumed a healing appearance. At this time, when the patient extended the arm, and suddenly a considerable quantity rose over the absorbing vessels, which passed along the inner edge of the large vessels. This quantity became nearly as big as a small grape. As this singular

and unknown depend on heat, and as there was no surrounding inflammation, I could not believe it venereal, and therefore recommended him still to abstain from mercury, and apply leeches and linen poultices to the arm, resting, and compress to the venereal part, and the inflamed abscesses. For it seemed to me that the venereal poison had been expelled from the sore, and would have caused inflammation and suppuration to take place there more slowly than had occurred in the present occasion.

Under this treatment the sore was healed, and the rest of the arm then healed. About two weeks afterwards the patient called on me, and said that there were venereal sores in his throat; and to each throat there was an ulcer deeply excavated, with irregular edges, and with a surface covered by granular matter; others, in short, which every surgeon who depends on his sight as his guide, would have pronounced to be venereal. Shortly after, this time, a new enlarged abscess appeared on his face and arm. He stopped his disease in several respects, as when opening the throat, who, without hesitation, affirmed that they were venereal, and that the constitutional disease had been long ago departed.

While the patient was looking over his history, in order that he might go through the remaining cases, he recommended thinking and reflecting on the particulars, pointing the finger to the abscess, a sign of the character of a hard crown abscess, and was, in short, what every surgeon tells is really only of his sight and touch, would, without reasoning, have called a true venereal abscess. I now told the patient that I was more inclined to believe his disease was syphilitic, from the nature and treatment, and the progress of this case with the rest of the arm. His surprise through differently, and I believe his very accurate and sensible mind was convinced that his health would be a sacrifice if he did not go to London to consult my opinion. He was preparing to return to a mercantile course, when very unexpectedly he called him suddenly into the country. In ten days, with great reluctance, taking with him venereal disease, &c.; and after a fortnight I received a letter from him, saying that he found his complexion improved in his journey, that business had prevented him from leaving the use of mercury for a few days, that he was found it was unnecessary, that his symptoms had almost disappeared, and shortly afterwards he became perfectly well.

Mr. Abernethy considers this case as the most unequivocal instance of cure of a disease which could not be syphilitic, he distinguished by symptoms of its greater experience from syphilis, and was, therefore, was undoubtedly of a different nature than is usually, it was of a different nature according to common opinion, then generally believed, but which some more sagacious have pointed to be destructive of buboes. All this time he refused to receive him within it in the foregoing columns. I still can remember them.

Some years ago the wife and was introduced at a society for syphilis. (See *Notes*.) In the presence of an officer being present in venereal disease it was first alleged, many symptoms have not appeared, though, in a female patient, has appeared, it has certainly been allowed, with some other symptoms, to require a kind of compensation with mercury, and admitted to be useful in venereal cases under certain circumstances. A great deal of this sort of argument on the effects of mercury is applicable most, it now explained by the imperfection of the diagnosis, and the important fact that the disease may proceed far beyond in time without any medicines whatever, though this case is sometimes long. In short, was first suggested the use of arsenic acid, has attempted to correct the alleged occasional failures by observing that the acid which he employed was not pure nitric acid, but an impure acid, containing an admixture of osmotic acid. He, therefore, was more generally recommended the use of a crystallized acid, containing three parts of nitric acid, and one of osmotic, which he administered internally, and also applied externally, liberally diluted with milk, until the gums were affected and profuse produced, and he continued every day an opium enema, when some constitutional effects occurred.

"The acid that I have used of late (says Dr. Abernethy)

to the intra-vascular; and it is formed by mixing together equal parts of the nitrous or uric acid and malarial acid. If these acids be in the state of combination they readily pass in the blood, and if the quantities be considerable, a great volume of gas is developed on their coming into contact, which distends every part of a horse, or, in extremely feeble individuals, every part of a human, to almost intolerable dimensions. I put a quantity of water, at least equal in bulk to that of the acids, into a bottle, and I add the acids to it separately. This method does not only prevent the unpleasant odor, but it tends to retain the chlorine, in which it is likely to deposit. It is well known, that the intra-vascular acid acts very readily on the vessels and earths, swelling, therefore, but glass or extremely well-glazed vessels of porcelain, should be used to contain it. Women who are bathing in some very well, and they should always be made as well as possible, compatible with their holding the body, at the time that they wish to expose to the bath. These things being duly considered, and we are able to avoid the bath with ease. In India, I have often observed the women who have been to the bath, but have not been satisfied, in general, with keeping the legs and feet exposed to it. In order to stain the bath after the first time, I have sometimes made third or a fourth part of it to be thrown away, and the rest replaced by fresh water and a proportional quantity of acid. To save the expenditure of acid, I have occasionally employed a portion of the bath in porcelain vessels, placed near the fire, but I find this very objectionable.

It is the very matter (testimony Dr. Scott) in given dimensions with regard to the degree of acidity of the bath. I have commonly made it about, or strong, as very weak strength, looking to the facts above. The strength should be regulated by the degree of irritability of the patient's skin. I may say, that although I like to know that it is strong enough to prick the skin a very little, after being exposed to it from fifteen to thirty minutes, yet I believe that even such an effect as this is unnecessary.

That the act of remaining in the bath in order to produce the greatest effect, is a matter of detail. I have kept the legs and feet exposed to it for half an hour at a time; but in some delicate people, sometimes one-half or one-third of that time. I have repeated these baths daily, or even twice or three a day. (See *Med. Chir. Trans.* vol. 5, p. 101.) Dr. Scott adds, that the more exposing the skin with intra-vascular acid sufficiently diluted with water, gives rise to the very same effects as bathing, and is more easily adopted. Fifteen or twenty minutes may be employed in the evening, though a much less time produces very material effects.

Dr. Scott has found the intra-vascular acid particularly useful even in this country, in that destruction of syphilis which is termed *proleptic syphilis*, and he attributes the beneficial effects to the chlorine, which is mostly combined in this compound. (See *Journal of Surgery and the Arts*, vol. 1, p. 225-231; *Lond. Med. Reports* vol. 7, p. 50; *Med. and Chir. Trans.* vol. 2, p. 172, &c.)

The only individual combination which I venture to draw from Dr. Scott's observations is, a combination of the fact of the generally available nature of syphilis, diseases without the aid of mercury. And I further observe, that though the intra-vascular bath may sometimes be useful, the great value of bringing it into disuse, is, in respect to an application to all forms of syphilis, for which neither this remedy nor even mercury will ever suffice. The nature of it has been most successfully employed of late years, but after the facts stated in this article, the alleged result of how much more must be entered with skepticism, and in particular the idea of these specific powers rejected.

The preceding notice is an elaborate one, upon the whole, as the question of the present state of our knowledge of the venereal disease, through the existing condition of conflicting opinions concerning the efficacy of the powers capable of inducing such a variety of results as are to be observed in syphilis affections, we are yet left in doubt as to what of the most important principles which ought to govern us in our treatment of specific diseases of the genital system. To Mr. Churchill the profession is in an especial manner indebted for such interesting matter on

the subject, and the facts which the more recent occurrence of the disease among the population may have furnished us are also to be cherished as of great practical utility. (See *Histories, Virgows, Gutter, &c.*)

The venereal mercury, and its syphilitic complications, who have appeared in the United States, deserve also to be treated with some care, inasmuch as not a few of these, from simple opportunities, have set forth many interesting views on these venereal questions.—See *Reviews in Philadelphia Medical Journal*, vol. 2. *Hygiene*, in *New-York Medical Reports*, vol. 1. See also vol. 4. *Acid*, in vol. 5. *Opium*, in vol. 3. *Mercury*, in *North Amer. Med. Journal*, vol. 1. *Water's Plan of Syphilitic Treatment*, in *Med. Communications*. *Proleptic Syphilis*, in *Med. Chir. Trans.* vol. 4, &c.]

Next to the question of the present day way to place our confidence in the satisfaction of opinion of Mr. Hirst, thus fully, and his doctrine of the identity of the poison of gonorrhea and syphilis, of his infallible diagnosis of chlorine, and, finally, his concept of the necessity of extensive salivation, have probably few advocates in America. Moreover, the latest investigations by Hirst and continental writers seem to have improved the title of possibility that such a claim could be made in behalf of these Hirstian principles.

That gonorrhea and syphilis originate from distinct poisons, and that moderate salivation only, or the merely salivating the system, is the influence of mercury, is as true as necessarily, is, perhaps, sustained by some of the most perfect specimens of the modern; and the foregoing authorities of Mr. John Hunter, of the London Lock Hospital, is relative to the inefficiency of the mercurial substance, have been discovered in the last time by pathological clinical dissection. I shall here insert as correct from an elaborate essay on mercury, by my friend Prof. Fuchs, written some time since, and the advocates for the mercurial system as were not so numerous as at present. The entire paper may be seen in *Hirsch's and Fuchs's American Med. and Pathological Register*, vol. 2, p. 4. To the introductory, what are the changes effected in the system by the influence of mercury? Dr. F. observes: "Little is known beyond concerning the possible nature of the virus of syphilis; the action which takes place upon the application of the smallest particle of mercuric matter to the human body, and the power by which it generates disease, converting it local into a general disorder, and thus producing an altered and vitiated state of the whole system, it must be admitted, are neither very known to the science, nor very clear in the reasoning process of man. The effects themselves, however, have been long and familiarly known, and from daily considering these, a rational theory may, perhaps, be formed of the manner in which they are produced."

That the power of specific diseases, as that of less venereal, small pox, &c., diffuses itself through the whole constitution, and produces into brown nature the general state of circulating fluids, seems to be more common to all than is understood of their peculiar character. Upon the introduction of a particle of venereal matter into the system, an inflammatory action of the part into which it is injected is excited; lymphatic action and mercurial matter of the same nature is generated. This process may be carried on to a greater or less extent, in a longer or shorter time, in different persons, before the specific external action is absorbed; and hence local inflammation is in some cases considerably advanced before the system becomes affected, while in others the mercurial action appears to be more or less to have made some little progress. The mercurial action, modified in its action by the degree of salivation, the condition of the part, and habit of body, is taken up by the absorption, and enters the blood vessels, whence it is conveyed to the general circulation, and produces its peculiar effects upon the constitution. The fluids themselves are therefore necessarily first affected, and as a consequence of their mercurial condition, the white threads are now become vitiated. Hence the modification of the nature of various coagula is increased mercurial; and hence, in the same principle, the generation of mercurial matter from a similar action, arising from the introduction of the other specific poisons. By the introduction of a specific mercurial matter into the body, its condition is changed from a healthy to a diseased state,

the local is transferred into a general disorder; the glands, and ultimately the system, become affected, and, according to the peculiar virus acquired, the whole constitution partakes in a greater or less degree of the venereal taint, whether it be syphilis, lues venerea, mercurial, &c." The theory of Mr. Hunter, and every theory which is salutary, changes, by creating a new specific action, and thus this is contrary to the specific factor lues venerea, is contradictory to the fact that two specific actions can exist at the same time, is shown by Dr. P. to be inaccurate and unsatisfactory, from the well-known fact, that it often happens that two specific diseases prevail simultaneously in the same individual, as we find recorded in the cases of Pilonis, Jenner, Haysmith, and others in the *Lancet*; and by every author on various diseases of an acknowledged specific character.

But the theory of Mr. Hunter is adopted to be overruled by other facts concerning the changes induced by mercurial action, for which I must refer the reader to the essay of Dr. P.—*Water, Med. and Phil. Register*, vol. 4, p. 480—492.

In addition to the narrative style of narrative in the treatment of these venereal, he remarks, "The action of mercury, though primary on the venereal system, is communicated to every fibre of the body, and produces a degree of rheumatism, acidity, and debility. When taken into the system, it manifests itself by a quickened circulation, gives the blood the disposition to stain the hairy coat when drawn, renders the pulse frequent and larger, increases the respiration, excites the temperature of the body, occasions a whitish fur on the tongue, and other symptoms of general inflammatory action. Its effects upon the secretions are still more apparent, producing a permanent flow of saliva, an increased action of the nervous vessels of the trachea, lungs, digestive organs, chyliferous vessels, and whole muscular system. It causes a copious discharge of urine, and in the smallest quantity excites an itching on the skin. In its excessive influence on the body, it produces an increased action of the absorbent vessels. These may be considered the same salutary effects of mercury, when its action is not particularly modified by the mercurial condition of the constitution." Dr. P., therefore, concludes, that from the very general stimulant operation of mercury in promoting the excretion of the whole system depends its curative action. "We further remark from these remarks, that from these perturbations of mercury which are here calculated to secure the general action, our next approved system of relief are to be drawn; and hence the difference between the two pills are to be perceived as possessing this character. We are still further strengthened in this view by observing the effects of elutriate on the venereal disease, and are enabled here better to appreciate the valuable facts furnished us by Mr. Carmichael. Accordingly, the persevering practice of Mr. Howard, and of the other writers, who advocate pure salivation have been resisted, and they that the treatment ought to "draw like a river," will find one of his objections to the present exaggerated state of knowledge. Indeed, it seems to be well established, that where salivation is early excited by a too free use of mercury, our chances of a permanent efficacious cure are actually lessened, and sometimes entirely cut off."

"There is another circumstance connected with the action and effects of mercury on the human constitution, which, though it does not strictly come under the consideration here, may nevertheless be mentioned. I allude to its propensity to the ulceration which a mercurial salivation produces, becoming a point of interest in judicial medicine as well as in practice. It seems to be well established on practical authority, that salivation, having commenced, when it is attended with marks, may readily be reversed by the slightest dose of mercury. Hagedorn and Howard, of the Lock Hospital give us facts of this sort. Mead mentions a case where the salivation was six months, and Hagedorn, of Edinburgh, relates a case of a long nature. In his lectures on venereal medicine, Dr. Francis informs us he has recorded two instances of a similar sort as his own practice, in which a few grains of mercury reversed a salivation which had been suspended for several weeks in one case, and in the other for more than eight months. The inference to be deduced from occurrences of this nature renders it necessary for us to enquire into the inquiry, whether the point should be aimed to mer-

cure for the cure of venereal disorder does to him as least practitioners under the operation of mercury, as perhaps ungenerously occur, and this I think is a question deserving consideration. The fact is, that mercury is given sometimes in syphilis, ought to be given in a constitutional propensity, prepared for the purpose, the power of the system after mercury is to be removed is much before we commence. With this entire acquiescence we shall find that such, or some other, all things be calculated before commencing with mercury in constitutions acquired by leprosy, and other causes. Dr. P. informs us, that in some instances he has given it as a salutary preparation directed to general, especially in cases of long-continued syphilis, some mercury had been previously anti-syphilitic."

The Institute of gold has not been attended with the success in the treatment of syphilis as was expected, which might have been expected from the effects of its chemistry alone. In my own practice it has been used in this city, it has proved to be best, that in some cases where mercury was considered only first, it was employed chiefly to diminish the pain, and diminish the venereal salivation occasionally induced by mercury. The learned Dr. Munk, formerly, of the practice of the New York Hospital, in which he introduced the method of Columbia in 1811, that that metal was capable of effecting salutary results. "Without pretending to affirm, that it is better to Dr. Duchamp (*Edin. Dispensary*, June 15, 1825), that it is capable of inducing the development of every instance, my opinion upon the whole is, that the nature of gold will effect it, but is not proved by patients of syphilis." Still more recently, but has been covered in satisfaction the cause of various preparations of mercury to the use of various success; and the article of 1822 is almost unchanged in his practice of gold as an anti-venereal remedy, as was Salvo's of 1806, which he pronounced it capable of radically drying all venereal humors and clearing out of the human body, syphilis and the French, because it purified the blood, and thus brought to the source of the disease. I feel assured, however, on testimony of Anthon's experience and success in his experiments, that their efforts will be made with that of the Academy of Paris, who, with the venerable Pavy at their head, have reported unanimously on the subject, and declared the metallic power of this substance remedy with some to be platinum and copper. (See father *Journal*, vol. 10, p. 111, written by Dr. Berthol.) For a variety of experience with the nature of platinum in syphilis, I must refer to the *Edin. and Science Med. art.* March, 1820. I am not aware that this article has ever been used by American physicians.

The author has made reference to the British paper of the late Mr. Hey, in the *Medical Agency*, *Trans. of London*, vol. 7. That paper is a valuable contribution to our stock of knowledge of venereal diseases. Mr. Hey is one of the earliest authors who support the opinion, that the venereal disease is capable of affecting the human system, as do the sermons of Mr. John Deane upon our condition in what the venerable Hey has advanced—*the Physician's Life of Hey*. That cases of this kind are already noted under the observation of the most practitioners cannot be denied; I have recently seen the disease thus reported. Many seem to be giving to prove sufficient on this point, and of this nature are also furnished by Professor Brown in his *Medical Essays*, vol. 2, and I myself, the author in some detail cases given by Professor Brown, his revised edition of Dr. Denham's *Medicine*. "I have, but under my own care," says Dr. P., "a case of the venereal disease communicated to us better in fact; two of these were venereal and the general system appeared in a perfectly sound state. Another three were others of the same kind, and venereal disease. In two the disease was apparent only after birth, and in one had been long elapsed before the disease manifested itself. Cases thus contracted are doubtless but rare, but the frequency of the venereal disease and the venereal disease in fact we can meet occasionally with the solution. See also *Dispensary*, Dr. P. *Pathology of the Venereal Disease*, who contends that an individual caught by mercury may communicate the disease. A valuable paper containing cases of venereal disease of the 19th

curved state of the laminae of the secondary cartilage of the ordinary lamina; a union of vertebrae and tail, and occasional escape of the muscles of the vertebral column. But, as Mr. Brodie observes, very similar symptoms may arise from other causes, and sometimes no particular symptoms are made prescriptive in the actual discovery of the curvature. (On Diseases of Joints, p. 270, 280.)

I have already mentioned Mr. Brodie's opinion, derived from dissection, that in many instances talipes of the spine has its origin in an alteration of the intervertebral cartilages, beginning in their centre, and extending to their circumference, and afterwards affecting the bodies of the vertebrae, which, in some cases, in other cases, the disease has its origin in the bodies of the vertebrae themselves, which are liable to the same peculiar disease of the spongyous structure, which is noticed in the vertebrae themselves of other bones. (On Diseases of Joints, p. 287.) This gentleman suspects that the disease, which begins in the cartilages, is the intervertebral cartilages, and that the first form of the disease, which becomes so extensive a destruction of the vertebrae, is the last. But (says Mr. Brodie) further than this, nothing which I have hitherto observed enables me to point out any circumstances in which the symptoms of these different diseases differ. (P. 284.)

Remembering another element, that when the laminae become so much affected, the symptoms depend on pressure or irritation of the spinal vertebrae, I cannot say that I accords with several cases which have fallen under my own notice; that is to say, if the affection of the lower limbs is to be considered as a sort of mark, limited or positive.

According to Mr. Pott, the true curvature is generally bilaminar, it being three spines outwardly, and it varies in extent, in extent, and in degree; it affects the neck, the back, or the hips; it comprehends one vertebra only, or two, or more; and as one or more are affected, or as three or four are affected, the curvature may be different.

In these cases, as Mr. Brodie remarks, "the distortion of the spine is usually of a peculiar kind, and such as nothing can produce except the destruction of the ligament of one or more vertebrae. The spine is bent forwards, so as to form an angle posteriorly; and although the destruction of the vertebrae may be the cause, it is more evident in some parts of the spine than it is in others. For example, the spine processes in the middle of the back being long, and projecting downwards, the elevation of one of these must occasion a greater prominence than that of one of the spine processes of the neck, which are short, and stand directly backwards."

Curvature of the spine, in the direction forwards, may arise from other causes, as a weak condition of the muscles, or a palsy, affection of the bones. In general, in such cases, the curvature comprehends the whole spine, which assumes the form of a segment of a circle. At other times, however, it occupies only a portion of the spine, usually that which is formed by the superior laminae and inferior dorsal vertebrae. But here, as Mr. Brodie has said, the curvature is always gradual, and never angular; a circumstance by which it is distinguishable from the curvature produced by cause. The cause, however, he thinks have often been contributed, and some speedily and completely cured of curvature more or less, he thinks, must have been cured by an entirely different cause. (On Diseases of Joints, p. 280, &c.; and *See*, in *Edinburgh Medical Journal*, Nov. 1855.)

"Lateral curvature of the spine is alleged generally to incline to the right side, and the fact is related (with what correctness I have not in the review process which is acquired by the spine present use of the right arm, and of other members in the performance of the voluntary actions." (On Diseases of Joints, p. 281.) It is admitted, however, that exceptions are not very rare, and that the lateral curvature sometimes tends to the left, and occasionally sometimes the latter is reversed. On this subject I have also another case exception to specify, which is explained by Mr. Brodie, viz. that though lateral distortion of the spine generally arises from causes independent of cause, a slight degree of lateral curvature is in some instances produced by the bodies of the vertebrae having been

destroyed on one side by caries, in a greater degree than on the other. (On Diseases of Joints, p. 284.)

In general, the lower limbs alone usually feel the effect. Mr. Pott, however, has seen two cases, in one of which the arms only were affected, in the other both legs and arms. Mr. Pott observed that a lad who had lost the use of both arms and legs from a carcinoma. An account of this singular example was also contained in Mr. Pott by Mr. Parks of Liverpool.

Mr. Brodie has never known the palsy affect the muscles of the arms; when the disease was at the lower or middle part of the spine; but he agrees with Mr. Copland, that the symptoms are not always confined to parts below the disease, and that it is not an constant for pain in the upper extremities to accompany the palsy in the lower limbs and thighs. (On Diseases of Joints, p. 285. Copland, *Obs. on Distorted Spine*, &c.)

Very soon after the curvature, some patients are rendered totally and absolutely incapable, not only of walking, but of using their legs in any manner; others can move about with the help of crutches, or by grasping their thighs just above the knees with both hands. Some can sit in an armchair without much trouble or fatigue; others cannot sit upright any longer. Others retain such a degree of power of using their legs, as to be able to shift their position when in bed; others have no such power, and are obliged to be moved upon all occasions.

I have been present at the dissection of persons who died of laminae distortion, and who, while they lived, never suffered the peculiar form of the lower extremities, as well described by Mr. Pott, though the vertebrae were found to be diseased. However, in some instances of such diseases, attended with distortion of the spine, the legs are deprived of their power. In relation to the difference in the curvature, the consideration that it is sometimes the disease of the lower limbs is secondary, and the disease of the spine is primary, I cannot determine. At all events, paraplegia is frequently only an effect, the curvature existing long before the disease; and in such cases, the legs are affected. Some time ago, Mr. Dandy, of Scarborough, consulted me about a case, in which the latter facts were ascertained. Mr. Brodie's opinion that paraplegia takes place at an earlier period, in cases where the disease begins in the spongyous structure of the bones, has been already noticed. In having a tendency to acute paraplegia, and in producing the weakness of the lower extremities, the present disease of the spine appears to be materially different from the absorption of the vertebrae, sometimes caused by the presence of morbid and other humors. (On Diseases of Joints, p. 280.)

Mr. Pott observes, when a child appears to be what the common people call naturally weakly, whatever complaint it may have are supposed to be caused by its weak state, and is generally believed that time and exercise will relieve them; but when a curvilinear has made its appearance, all these marks of weakness, such as laborious respiration, hard cough, quick pulse, listless face and limbs, pain and rigidity of the muscles, &c., are mercifully ignored and set to the account of the deformity consequent to the spine, more especially if the curvature be of the dorsal vertebrae, in which case the deformity is always greatest; but whenever will carefully attend to all the circumstances of the disorder, will be convinced that most, if not all the complaints of children laboring under this deformity, proceed the curvature, and that a mortal state of the spine, and of the parts connected with it, is the original and primary cause of both.

Among many other reasons for thinking that an effect was mistaken for a cause Mr. Pott enumerates the following:

1. "That he did not remember even to have seen the useless state of the limbs from a mere malformation of the spine, however cured with immobility might have made it."

2. "That some of these deformities from right shape which growing girls are so liable to, however great the deformity might be, was not attended with ill effect."

With respect to the treatment of distorted spine, I think was principally laid down by Mr. Pott, and is now generally adopted, viz. that the primary and sole cause of all the symptoms is a distorted state of the parts,

thoroughly washed, and surrounded with dry compresses. This dressing adheres both to the toes and the fingers. I have very observed, close the great toe, and more frequently on the thumb, than any of the fingers. In regard, too, chiefly to young people: I shall have also seen a whitlow affected with it.—(Partridge, in Med. Chirurg. Hist. &c. p. 125, 126.)

The causes of whitlows are generally of a local nature. Whilst examining the swelling as the most essential, a surgeon, suddenly wounding the finger when it is exceedingly red; pricks with needles or other sharp instruments; and the introduction of irritating matter (as mercury in the finger). A surgeon, in operating for a felon, has been known to cut the finger, and have, in consequence of the accident, a very severe and dangerous kind of whitlow. Butcher also mentions a person, who had a spot, whitlow, whitlow, in consequence of a slight wound on the finger, in examining the head of a horse that had the glanders. Remains the danger of a whitlow depending on a splinter or thorn which sometimes lodge in the part. Very often no particular cause whatever can be ascertained for the complaint.

The first cure, which occurs, about the root of the nail, ought to be opened as soon as possible. When the pus is not abundant, the matter is not so general, and may be cut, near the root of the nail, and decompose, at least this part. When an effluvia opening is not made, the matter collects again. In general, a dissection of the whole takes place as far as the disease extends. When the inflammation has been very violent, and the matter has made its way as far as the root of the nail, the nail itself often grows gradually detached, when the detached portion of the root of the nail acts on the sensitive finger, and makes it more itching. Hence, the surgeon should repeatedly cut away at many of the former edge of the nail as he can, and substitute a little oil of turpentine on the edge of the nail and the skin, in order to keep the latter from being irritated by the former. In proportion as the nail and gradually separates a new one makes its appearance.

When matter lies under the nail, an opening should be made through the part as speedily as possible for the discharge of the abscess. In order to perform this operation, Raker takes the surgeon by scrapping the nail with a piece of flint till it is so thick, it can well be, without any further things with a bistoury.

In the worst species of whitlow, suppuration may sometimes be prevented, and the inflammation be removed by the timely employment of potent means. When the pain is violent, and some fever prevails, it may be advisable to bleed the patient. In a few severe cases, the application of three or four leeches to the affected finger has been known to produce prompt relief.—(Schwartz.) Thence, it follows, that applying a relief round the finger, little, and around the finger, nothing the first two parts with a leech, and the third with a leech of removing the inflammation. Parow advises the finger to be for some time immersed in water as warm as the patient can bear. Some recommend the external use of emollient spirit, or the hyposphragmatic; while others advise the affected finger to be plunged in warm solution of soap, or in warm lotion. When the whitlow is attended by a great, painful, and even the skin will not extrude, suppuration remains in the patient.

When the suppuration does not show by the fourth day, Raker recommends an opening to be made. Even when an abscess is discovered by opening of making a small incision in the skin of the joint, and by pipes, that although no matter made is discharged, the patient always derives relieve relief from the operation. The incision, he says, may either be made in the fleshy part of the disease of the last three days, when suppuration the subsequent inflamed pus, flattens the inflamed matter can be plainly felt, and, in this case, there can be no hesitation about the place where the opening should be made. However, it may be better to remark, that the opening should always be made sufficiently large. When the finger makes a violent puncture it soon closes again, and a repetition of the operation becomes necessary. When opening the abscess is delayed, the throbs of the finger renders easily becomes affected, as the matter may spread to a considerable extent under the skin. Sometimes it makes its way through the nail as whitlow,

and takes by the article. In this case, as soon as the nail has been opened, a discharge should be introduced into the opening in the skin, and the matter opening be washed with a history.

The third species of whitlow seldom affects the last phalanx of the fingers, but generally the second or third. In this case, Raker advises us never to defer making an opening longer than the third day. If we wait till suppuration happens, we shall wait till the tendons are destroyed and the use of the finger is lost. In the case under consideration, the matter is always of bad quality and very small in quantity. A dissection in the finger can seldom be left. However, in a few instances, the matter penetrates to the extremity of the finger or about the finger joints; but never enters in the palm of the hand, or near the wrist. In these circumstances the tendons are in general already destroyed, and a stiffness of the finger and hand is to be apprehended. When the complaint is the consequence of a puncture, the best plan, according to Raker, is to open to enlarge the wound; for, in this sort of case, all other methods are unavailing. It is not enough, however, to cut through the skin; the tendons there must submit to incision.

When a collection of matter forms towards the wrist, attended with violent pain in that situation, an opening must also be made there. If an opening should have already been made in the hand, a probe may be introduced into the wound, and another operation made in an oblique situation by cutting at the neck of the instrument. In the same way Raker advises an opening to be made in any part of the forearm, where great pain, or the symptoms of suppuration may indicate its propriety.

In the fourth kind of whitlow, early incision made downwards to the bone are the most certain means of obviating the danger. When such incisions are not made early enough, suppuration takes place, and the bone perishes. The cut is to be made in the place where the pain is most severe. When the first phalanx is affected, the incision may be made in front of the finger, but when the second or third is the seat of the complaint, the opening should be made on one side. However, in order that the opening may be useful, it is absolutely necessary to make it down to the bone. When the incision is delayed too long, a small quantity of unhealthy matter is usually detached, and the bone is found in the state of necrosis. As an inflammation can hardly be expected in this situation, it is best to remove at once the diseased piece of bone. When the last phalanx alone is affected, the finger remains as firm, with the exception of its root being a little shorter and flatter. When the disease, however, is seated in the first phalanx, Raker thinks it better to amputate the finger than remove the diseased bone, as the finger, if left, would always remain stiff and unserviceable.—(See *Deformation der Fingerglieder*, vol. 7.)

With regard to the treatment of the species of whitlow named by Mr. Whistler, says a surgeon, all local applications have in many instances proved quite inefficient, and the part has been amputated. The only best treatment which Mr. Whistler has ever seen relieve his complaint has been the excision of the nail, and afterwards the external application of escharotics to the affected portion. I have myself seen a similar plan successfully carried, and the applications which appeared to answer best were arsenical lotion, Raker's escharic, or a very strong solution of the nitrate of silver. Nothing, however, will avail, till the nail is removed, and its total separation sometimes takes up a good deal of time, unless the patient submit to the great pain of having it cut away.

In both cases of the so-called whitlow, Mr. Whistler tried with success the exhibition of mercury. It was given in small doses at first, and afterwards continued, so as to affect the gums in about twelve or fourteen days. When the system was in this state, the sores in general soon answered a healing appearance, and the whitlow, which gradually disappeared.—(See *Med. Clin. Trans.* vol. 5, p. 126.)

The J. R. Whitlow, of Charleston, S. C., informs me, that in cases of whitlow, when by neglect or untimely treatment the bone becomes necrotic, he has frequently preserved the member by a timely resort to the diseased bone. Previous work in the habit of using the probe, and when whose *Whitlow* & *Whitlow* ch. 22, 23

taining the use of the thumb and fore-finger, and the subject to follow the operation in such a manner as to be beneficial. Dr. W. has several times received the loss of the first phalanx, and twice that of the second, and still preserved sufficient dexterity of the member to use it with tolerable despatch. The other fingers, under similar circumstances, may be supported with out materially interfering with ordinary manipulations.

This disease is so often regarded as unimportant by kind practitioners, that in the cases alluded to, it is often important to be possessed of a remedial means at once to production and its abatement.—*See* *Fracture*.

WOUNDS. A great deal of the subject of wounds has been already considered in the articles *Gun-shot Wounds*; *Head*; *Injury of the Head*; *Neck*; *Hydrophobia*; *Pericardial Disease*; *Scabies*; *Typhus*; *Throat*; &c.

A wound may be defined to be a recent laceration of externally in the soft parts, suddenly occasioned by external causes, and generally attended at first with hemorrhage.

Wounds in general are subject to considerable variety in their nature, degree of danger, facility of cure, and the consequences which are to be apprehended from them. Some wounds are quite trifling, not extending more deeply than the skin and cellular membrane, while others are very serious and dangerous, penetrating the muscles, vessels, large blood vessels, and nerves of importance. There are also certain wounds which are not confined to the soft parts, but rupture the bones; such are, really, calcareous, which frequently separate at once from a portion of the plate, and the suppurated part of the skull. Many wounds of the head, chest, and abdomen require the organs contained in those cavities. In short, the varieties and the degree of danger attending wounds, in general, depend very much upon each of the following circumstances: the extent of the injury; the kind of instrument with which it has been inflicted; the violence, which the edges of the part have suffered, in addition to their division; the size and importance of the blood vessels and nerves which happen to be injured; the nature of the wounded part, as respect to its present power of healing freely, or not; whether the operation of the system at large, and life itself, can be well supported or not, while the functions of the wounded part are disturbed, interrupted, or suspended by the wound; the youth or old age of the patient; the good-nature or badness of his constitution; and the opportunities which there may be of administering proper surgical aid and assistance of every kind.

All wounds of considerable size or depth, not producing immediate death, are followed by more or less disturbance of the whole constitution; by a fever, which, on account of its being an effect of the local injury, is sometimes called *symptomatic*; and some times *suppurative*, in consequence of its being, as it were, the sympathy of the whole system existing with the wounded part. It is likewise frequently attended by a secondary fever, in consequence of the wound, or severe inflammation. A suppuration it will be found in another part of this work.—*See* *Fever*.

Wounds, especially those of the lungs and liver, and other tendinous parts, are necessarily productive of serious forms of constitutional disturbance, affecting to a violent degree the vascular system, and well known by the name of *fever of the wound*. Of this I have fully treated in another article.—*See* *Fevers*.

Profusely suppurating wounds, the cure of which is retarded by any accidental circumstance, invariably being on great debility, and a particular disturbance of the constitution, increasing, digestive, nervous, and other systems, known by the name of *fever of the wound*, which I have also delivered on at length.—*See* *Fevers*.

Another classification of wounds, often met with in crowded military hospitals, is a peculiar variety of suppuration, frequently supposed to be contagious, and already described in the article *Napoleon's Green*.

Besides these consequences of wounds, it is my duty to mention another very common one, which seems to be intimately connected with the patient's temperament or habit of body. I here allude to *erysipelas*, which may be excited by a wound, instead of healthy suppuration inflammation.—*See* *Erysipelas*.

I may as well here observe briefly about the various complications of wounds, namely, the absorption of callosities in the liver, lungs, around the joints, or in other im-

portant organs, attended at a considerable distance from the wounded part. These accidental suppurations in the liver and lungs, after injuries of the liver, have been ascribed by authors for the last sixty or seventy years. They have been noticed by Le Dran, Deharrois, and others; and they have again been recently brought into consideration by Mr. Ross and Mr. Anst.—*See* *Med. Chir. Trans.* vols. 14 and 15. The late war has corroborated, that they may depend upon the absorption of some specific matter from the wounded part, and as I have elsewhere detailed (see *Fract.*), the peculiar fatal symptoms of phlebitis, in which similar abscesses are frequently formed in the vessels of around the joint to the same cause, and under the influence of the inflammation along the track of the vein to the sinuses, and even the heart.

Wounds are distinguished by surgical writers into several kinds. viz. *Wound*, *punctured*, *contused*, *incised*, *perforated*, and *gun-shot wounds*. These are some of the most important divisions into *Wounds of the Head*, *Throat*, *Abdomen*, &c.

Of punctured wounds, and wounds of the lung, as is contained already been given.—*See* *Gun-shot Wounds*, and *Head*, *Abdomen*, &c. The other cases I shall now proceed to consider.

Incised Wounds.—An incised, otherwise it may be termed *sharp* or *cutting* wound, is a wound which is made with a sharp cutting instrument, which is usually a knife; however, it is attended with but trifling or no serious consequences, than any other kind of wound, wherever. The blood there only flows slowly down; they have suffered no laceration of the nervous system, and are therefore less likely to produce death, it is impossible to stretch, and they sometimes unite by being united again in a very expeditious manner.

Generally, sharp incised wounds heal more easily than contused and lacerated ones, which at the same time, however, may not say based on all accounts, considerable blood vessels may be injured. But in the case of incised wounds, apparently discharging the danger of blood and lacerated wounds, hemorrhage, and even death, to render the case in reality more serious, by so doing the uncorrected practitioners to be of to guard against hemorrhage. Thus, incised wounds often happen that on their first occurrence the bleeding is trivial; but the side of some large artery being lacerated, great violence at the blood of the artery may be liberated at length, a work in the hemorrhage, and in alluring, and even fatal, effects of blood to the result.

In cases of sharp incised wounds, the bleeding, which at once takes place from all the blood vessels, is a source of great useful information to the surgeon, inasmuch as it enables him to judge what kind of blood vessel is lacerated, even the hemorrhage, whether the blood vessels are large enough to demand the ligature, or the contrary, whether they are such as will close by themselves by slight pressure or not, and so forth.

In a recent sharp incised wound, where the blood vessels which the surgeon should endeavor to stop, without the least delay. The first and best thing requires his immediate interference, is the bleeding, which must be checked. The second is the removal of all extraneous matter from the surface of the wound. The third is the removal of the opposite side of the injury.

When the divided vessels are not above a certain size, the bleeding soon spontaneously ceases, and all surgical measures need be taken on this point. If the wound is large, and the vessels are of considerable size, and their situation is favorable for uniting, with or without, it is often advisable to shut the wound and apply compresses and a roller, under the have means to hasten, which always makes a certain degree of uniting and suppuration. However, though I have used this description, I should be extremely sorry to appear at all against the general practice in ligatures, whenever the wounded vessels are above a certain magnitude. In this circumstance, by the bleeding vessels is actually kept in a state of coagulation. When the artery is of considerable size, and its mouth can be readily seen, the most proper advice would be to take hold of it as a part of the vessel. In applying the ligature, the surgeon must take care to put the ends as well as another that the vessel will not slip, the result of the event, and for the purpose of showing the direction of the force necessary to repair

ing the ligature, the ends of the threads are generally turned up at it. The intention is obviously to prevent the taking up of adhesions, which are necessary and desirable.

These ligatures, of sufficient strength, are at present often applied, as well to large as small vessels, as a preventive, in the establishment of which the experiments of Dr. Jones, and the writings of Dr. Voisin, are generally remembered. One tail of each ligature should always be cut off before the vessel is closed, and there are many surgeons who prefer the method of cutting off all the ligatures, except what forms the knot immediately round the artery.—(Edinburgh, *Ann. sur la Pratique d'Aliment*, p. 29; *Lancet*, in *Med. Cas*, Trans., vol. 6, p. 154.) At the latter point, however, a few surgeons have advanced objections, particularly Mr. Gosselin, who only admits the utility of it in cases where the wound will not close by the first suture.—(On *Wounds of Wounds*, p. 54; and Mr. Erwin, of Norwich.—(See the *Lancet*, *Medical Repository*, vol. 7, p. 33.) The importance of the case used in the following experiments.

First, if the wounds do not unite by the first intention, the ligatures may interfere with the discharge, without any inconvenience.

Secondly, if cerebral ligatures of vessels are cut short, the wound may unite over them, and they may be found to decompose after an interval of every week.

Thirdly, if the large arteries are to be employed in the same way, and the wound made over it, the ligature may be detached from the vessel, and moving about it is an abscess, where it may be found at different periods, from one to seven, weeks; and this may happen, whether the vessel be directly compressed with a single ligature or divided between two ligatures, as is to illustrate the circumstances under which vessels are treated in operations.

Fourthly, if Italian silk, free as when, be put straight round, as into a glass, as a measure, or instead of modification, by, and compressing of sides together, it may require, in this situation, without exerting absorbent, or producing any inconveniences. The ligature may be thus applied to compress the artery for the cure of aneurism; but not to secure vessels divided in operations. If a distal figure be drawn sufficiently tight upon a vessel on the face of a lump to be excised, Mr. Gosselin perceived, that the utility of the vessel which he was secured, as it were, was lost.—(See *Lancet*, *Med. Repository*, vol. 7, p. 302.) It deserves attention, that the preceding instructions are clearly founded on experiments made upon dogs and dogs. For further observations, see *Observations, Mémoires, &c.*, *Lancet*, *Medical Repository*, &c.

The bleeding having been suppressed, the next object is to remove any extraneous matter, such as dirt, bits of glass, slabs of wood, &c., from the surface of the wound. Were the circumstances neglected, the play of nature the ligature sides of the cut by the adhesive inflammation, or by which is more frequently termed, union by the first intention, would be generally frustrated.

As soon as attention has been paid to the foregoing indications, the surgeon should put the lips of the wound in contact, and take measures to keep them there in this state until they have grown firmly together. The sides of incised wounds are kept in a state of apposition by means of adhesive plaster, in paper pessaries, the pressure of a roller, and, in a few particular instances, by the employment of sutures.

With respect to ligatures, as they excite pain, irritation, and some degree of suppuration, they should never be employed when the pain can be kept in contact without them. However, certain cases require them, and it is advisable to keep experienced witnesses that in other wounds of the ear, eyelids, nose, and lips, it is proper to use them.—(See *Lancet*, *Medical Repository*, p. 15.) An account of the several kinds of suture, with remarks on their employment, will be found in the article *Sutures*.

The best and most common method of keeping the surfaces of divided parts in contact is by means of strips of adhesive plaster. When they are to be applied, the surfaces should put the wounded part in position in the position which is most favorable to bringing the two of the wound together. With this view, a patient should generally be placed in which retains the skin and subjacent muscles. An excision should then place the edges of the wound as nearly together as possible,

and hold them in this state until the surgeon has secured them, by the continuance of strips of adhesive plaster, applied across the line of the wound. In general, it is proved by holding in between small interspaces of about a quarter of an inch between each two strips of plaster, by which means the wound cannot be widened in case of suppuration. Over these first strips, and so to be applied and kept in the place with other pieces of adhesive plaster. Then, if necessary, a plaster and compressure is to be put on the face, and, lastly, the bandage or roller is to be applied.

In the manner the fresh-cut surfaces are brought into contact, and to preserve them gently in this state, in the next point was which the surgeon should have in view. The wounded part should be kept in the position which was found the most favorable for approximating the sides of the cut at the time of applying the dressings, and the patient should be directed to keep the part in a perfectly quiet state.

When attention is paid to these circumstances, if all goes happily, then the two opposite surfaces of the wound grow together easily in the course of forty-eight hours, without any degree of suppuration. The process by which this disintegration is accomplished is well known, being supposed to be the result of union by the first intention. Besides the advantage of the cure being effected in this way with the greatest expedition possible, there is still another thing worth in favor of economy, preserving the method of healing wounds, which is, that the scar is much less than after any other mode of treatment, and the pain is covered with original skin, which is always much stronger than any which can be formed by a substitute force.

It is wonderful with what celerity union by the first intention takes place under favorable circumstances. In the course of three days, the large wound, made in the operation of amputation, is frequently all healed, except just where the ligatures are retained.

When the two sides of the wound have been brought together, before the healing of blood has entirely ceased, Mr. Denon conceives, that blood itself becomes the first bond of union; but on this point, Professor Thomson of Edinburgh, expresses a doubt; and all profess and surgeons agree, that the adhesion of blood on the surface of a wound is more likely to prevent, than promote, the union of the parts. In all common cases, what Mr. Denon calls the adhesive inflammation takes place. In two weeks, conglutinating lymph fills the space from the lacerated surface of the vessels, or from the surface of the opened cells of the cellular substance. This becomes the first applied medium, and very soon afterwards, in some insuperable manner, a vascular membrane is established between the opposite sides of the wound.

The power which parts of the animal body have of thus growing together, is strikingly evinced by the possibility of removing a part of one body, and then making it to some part of another. In this latter case, there can be no union given in the union of one side, since the detached part, as Mr. Hunter observes, can hardly do more than 140 pressure on its own living principles and attempt to heal. In this way, says the same writer, the space of the young cock can be made to grow on its comb, or on that of another cock, and afterwards, after having been removed, may be made to unite in the inside of any cavity of an animal.

Every one acquainted in surgery has heard of the facts of Tullius, Galienus, and others, who are said to have succeeded in effecting the union of parts, which were completely severed from the body. Several other not less extraordinary performances by modern surgeons are recorded.—(See *fact*, on *Adhesion*, with *case* *dissemination* of the *Parts of Nature* in *reproduction* *Parts* which have been by accident totally separated from the animal, See *Notes*, by *Wm. Bristow*, *London*, 1804.) Indeed, the post-mortem proof of the possibility of the union, the experiments of Dr. Hunter and Hunter, and the numerous and respectable characters of the testimony upon this subject, fully convince us of the possibility of union which may attend the endeavor to bring about such a union. Experiments also fully prove the frequent success of an endeavor to unite a part, which is united by the first intention of a small piece of flesh, or even a few shreds. My friend, Mr. Lawrence, attended a case which illustrates the truth of this statement. A man on the top of a stage coach was carried under a gateway which did not leave

the surgeon must carefully do it to take care of the health. When the wound does not suppurate favorably, the discharge generally becomes profuse, stinky, and glairy. This state is to be attended by bark, wine, rich diet, and good air.

I shall conclude this subject of union by the first intention, with an extract from the writings of Mr. Hunter, who observes, that

"It is with a view to this principle of union, that it has been recommended to bring the sides (or lips) of wounds together; but as the natural elasticity of the parts subsists some time, it has been found necessary to supply, not for that purpose. This necessity first suggested the practice of sewing wounds, and afterwards gave rise to various inventions in order to answer this end, such as bandages, working plasters, and ligatures. Among these, the bandage commonly called the *strapping bandage* is preferable in all the rest, where it can be applied; but its application is very confined, from being only adapted to parts where a roller can be used. A piece of sticking plaster, which has been called the *dry suture*, is more general in its application than the strapping bandage, and is therefore preferable in many occasions.

I can hardly suppose says Mr. Hunter, a wound is any situation where it may not be applied, excepting penetrating wounds, where we reach the lower portion of the wound to be closed equally with the upper, as in the case of the lip. But even in such wounds, if the parts are thick and the wound not deep, the sides will seldom recede in so far to make any other suture necessary. The dry suture has an advantage over stitching by bringing a large surface of the wound together, by reflecting the parts to which it is applied, and by continuing producing an inflammation, and absorption, which still keeps it close. When parts, therefore, can be brought together, and especially where some force is required for that purpose, from the skin will bring it close generally, the sticking plaster is certainly the best application. This happens frequently to be the case after the removal of tumours in scapulars, or when the sides of the wound are only to be brought together on one side, as in the knee-joint; and I think the difference between Mr. Hunter's cross-stitch suture operation as recommended in his *Crural Inquiry*, and Mr. Alcock's practice, states strongly the superiority of the sticking plaster for dry suture. In those parts of the body where the skin provides more than in others, this treatment becomes less necessary; and as the parts probably recede as little as any, it is therefore sufficient necessary to apply any thing is requisite of that part, the suture will certainly answer but is superficial wounds, because the distance is in these cases within its influence.

The sticking plaster should be laid on in strips, and these should be at small distances from each other, and should be greater of an inch at night, if the part requires this confinement; but when it does not, they may be at greater distances. This precaution becomes more necessary if the bleeding is not quite stopped, there should be passages left for the exit of blood, as the accumulation might prevent the union, though this does not always happen. If any sanguine body, such as a ligament, should have been left in the wound, suppuration will take place, and the matter should be allowed to rest at some of those openings or spaces between the strips of plaster. I have known a very considerable abscess formed in consequence of this precaution being suggested, by which the whole of the recently divided parts have been separated.

The interrupted suture, which has generally been recommended in large wounds, is still in every but useless process equal to the intention. This we may reflect to be the only one that deserves the name of suture; it was formerly used, but is now not practised, even laid aside as useless, and from the impossibility of uniting parts by this process, but from the accident, and mode of attempting it. In what manner better methods could be contrived, I have not been able to suggest. It is to be understood that the sides and ends of bringing wounded parts together in order to unite them, are only to be put in practice in such cases as will admit of it: for if there were a method known, which, in all cases, would bring the wounded surfaces into contact, it would in many instances be improper. At some wounds are attended with tumours, by which the parts have been more or less detached, in such

cases, as was formerly observed, union cannot take place according to the first principle, and therefore it is improper to attempt it.

In many wounds which are not attended with contusion, when the other layer is subject that extravasated blood has been introduced into the wound, union by the first intention should not be attempted, but they should be attended as suppurative, in order that the suppuration may be effected. Wounds which are attended with laceration, although free from contusion, cannot always be united by the first intention; because it is not frequently to be expected to bring the external parts or skin so much in contact as to prevent that suppuration which is naturally produced by disunion. But even in cases of simple laceration, where the external surfaces are not jagged, or can be presented (as we observed in healing of the compound fracture), we find that union by the first intention often takes place, the blood which fills up the interstices of the lacerated parts, having prevented the entrance of impurities; it then and prevented suppuration, and afterwards is absorbed.

Many operations may be so performed as to admit of parts healing by the first intention; but the possibility should be sought with great circumspection; the mode of operating with that view should in all cases be secondary, and not a first consideration, which it has already been too often being neglected. In cases of cancer, it is a most important object, as to prevent suppuration.

In the laceration of wounded parts by the first intention, it is hardly or never possible to bring them so close as to prevent the exposed edges as to unite them perfectly by these means; such edges are therefore obliged to unite another method of healing. If kept moist, they will inflame as deep beneath the cut surface as the superficial as the union, and these suppurate and form a scab beneath, and above the cut edges, thus inflammation and separation of these edges will be prevented, and this will complete the union, as will be described by and by.

As those effects of accidental injury which can be cured by the first intention call up most of the powers of the constitution to assist in the repair, it is not the least affected or disturbed by them; the parts are united by the extravasated blood alone, which was thrown out by the injury, either from the divided vessels or by coagulation of inflammation, unless a single point taking place even in one part there, except the closing or coagulation of the vessels; for the flow of the blood as it is considered as equally essential. Even in cases where a small degree of inflammation occurs, it is merely a local action, and is notwithstanding the coagulation is not affected by it; because it is an operation to which the power belonging to the parts themselves is fully equal. The inflammation may produce a small degree of pain, but the operation of nature gives sensation of any kind whatever."—*Hunter on the Blood, Inflammation, and How that Wounds.*

Closed and Lacerated Wounds.—*Lacerated* wounds are those in which the fibres, instead of being divided by a cutting instrument, have been torn apart by some external rupture of overstretching their force of adhesion. The edges of such wounds, instead of being straight and regular, are jagged or unequal.

The wire suture is applied to wounds lacerated by some blunt instrument or surface, which has violently struck a part of the body.

These two species of wounds greatly resemble each other, and as they require nearly the same kind of treatment, they usually treat of these together.

Lacerated and contused wounds differ from simple wounds in appearing, as first view, fresh and alarming than the latter, while, in reality, they are in reality more dangerous. In simple cut wounds, the attraction of the parts and humors are not so much considerable than in a lacerated wound of the same size. However, notwithstanding these considerations, they commonly admit of being healed with far greater ease. It is worthy of particular notice, that lacerated and contused wounds are not so general attended with any serious effusion of blood, even though large blood vessels may be injured. I say in general, because, in the year 1812, I saw a soldier whose death was ac-

drawn by a sudden effusion of a very large quantity of blood from the internal jugular vein, which vessel had been injured by a musket-ball, that had entered the sternum, and lodged in the mediastinum, and passed obliquely downwards and forwards towards the axilla. The blood did not issue externally, but formed between the integuments and the wound a large dark-colored swelling, which produced almost insupportable suffering. At the moment of death, the patient, Professor Ainslie says a surgeon, who left the patient, said that he was injured by a musket-ball, the depth of the wound being a few inches.—*Am. Journal of Medicine* at Chicago, p. 32, March, 1842.

It would seem, however, there is at least one instance of a musket-ball from a distant part of the body, and it is a circumstance that often leads to a misapprehension in medical practice, by inducing them to pursue too much in the pursuit which they pursue. Surgeons named in practice, however, do not allow themselves to be deceived by the absence of hemorrhage, and in proportion as there is little bleeding, they apprehend that the violence done to the artery and veins has been considerable. What is it, that the continued and increased nature of the trouble, that prevents hemorrhage from the vascular system, when actually divided and severed with their knife? What facts have frequently been taken from the body without any hemorrhage of consequence taking place.

In the *Phil. Trans.*, Crookes has recorded a very singular case, at which a man's arm was suddenly torn from his body. Samuel Wood, a writer, had seated his arm a horse, which was engaged with the wheel of the mill. He was afraid of the horse, and then, seized by a horse, which presented the back of his arm, at this instant the wheel, which was turning with immense force, completely cut and carried away his arm and scapula from his body. The appearance of a wound occurred in this manner, and it seems to be a very rare case. The first idea that occurred, was, naturally, that the patient cannot possibly survive. Samuel Wood, however, died with his life. The first had been torn off with such velocity that he was unaware of the accident till he saw his arm falling down on the wheel. He immediately descended by a narrow ladder from the wheel, and even walked some paces, with a view of seeking assistance. He soon fell down from weakness. The person who first came to his assistance, covered the wound with powdered sugar. A surgeon, who arrived at the spot, observing that there was no hemorrhage, was content with dressing the skin, which was very fine, so as to make it cover the surface of the wound. For this purpose, he used two coats of plaster. The patient was conveyed the next day to St. Thomas's Hospital, and put under the care of Mr. Fern. This practitioner employed the usual means for preventing the bad symptoms from being expected in this sort of case. The first dressing came away without any bleeding; no alarming consequences ensued; and the patient is now perfectly recovered.

When the arm was amputated, it was found that the vessels inserted into the scapula were torn through near their insertion; while other vessels, arising from this bone, were carried away with it. The artery carrying the vessels had remained in its natural situation, and was not at all injured by the division precisely at the insertion of the blood vessels.

At La Haye, *Trans. des Académies*, may be found an account of a little boy, who, while playing near the wheel of a mill, got his knee, forearm, and arm successively engaged in the machinery, and the third time he was torn away at the shoulder-joint, in consequence of the huge body not being able to pass in the division in which the arm was drawn. The bleeding was so liberal, that it was stopped with a little flax, and the boy very soon recovered.

In the fifth vol. of the *Archiv. Med. Chir.*, Gosselin gives an account of the history of a child three years and a half old, whose arm was torn off by the wheel of a mill. Mr. Gosselin, who saw the child about six hours after the accident, found it almost in a dying state, with cold extremities, rising internal action, and on the left side of the body convulsed. However, there was hardly any bleeding. The arm was broken above the elbow and a half above the elbow (the stump had a blooded appearance); all the soft parts were in

a depressed and lacerated state, and the forearm was not broken high as the articulation, which was not exposed. The skin and muscles were injured by a much greater extent, and in different directions. The remainder of the humerus was removed from the shoulder-joint by dissection, only as much skin as muscle being left as was sufficient to cover the wound. In two months the child was well.

In the *Ann. de Chir.*, de Chir. 1. 2, is an account of a leg being torn away at the knee-joint by a wheel. The patient was a boy, about nine or ten years of age. This accident, like the foregoing one, was accompanied with no hemorrhage. The lower portion of the os femoris, which was exposed, was repaired, together with such portion of the soft parts as was in a continued and lacerated state. The patient experienced a perfect recovery.

The preceding cases strikingly teach the common error which I have already made, in regard to the bleeding from wounds arising from arteries and lacerated wounds.

In these instances, the pain is often so intense, that the cause of the accident; it is generally very severe, when the wound is very extensive, and is not the other hand, when there has been a strong degree of constriction, as in cases of injury from the action of the pump, the patient seldom complains of pain at all.

When the lacerated artery has not been exposed above a certain degree, the pain is generally not that intense as the wound, as they cannot get into the deeper, lacerated one, and are one of the few exceptions. Constriction, nevertheless, is found, and the degree of constriction is regulated by the amount of the wound.—(See this work.)

When a still greater degree of violence has been done, and especially when a portion of a limb is torn off, the pain is not so intense, and the patient is not so much distressed. However, if the constriction is good, and the patient not so much distressed, it is not so good and well. But, in other instances, the pain is extremely distressing, for the pressure of the blood in the wounded part, which has cut off the flow of the blood, is continued, and the patient frequently complains of such pains as were not at all interrupted by the blood itself.

The identification arising directly from the rapid organization of parts is not what is the most striking circumstance. A still more important kind of identification is that which is apt to be mistaken for the most inflammation produced by the wound. The consequence of the rapid organization of the parts of the wound, when made not to be mistaken for the identification, with the view of identifying the identification before it has attained this high degree, and the various symptoms have commenced. In the absence, he should not be afraid of using the most liberal a little, if it should be deemed to do so. The edges of the wound should then be gently drawn towards each other, with a few strips of dressing, so as to lessen the extent of the exposed surface, so as to be more proper. Indeed, the plan of increasing the exposed surface of a compound wound with the view of inducing granulation is not altogether good, and their application creates a liberal degree of inflammation. The method is chiefly applicable, when there is a large flap of skin, which can be immediately brought over the wound. In other cases, it is best to leave the parts free, uncompressed, and exposed with the view of better planity, because, if more exposed, it would do harm, and could not possibly produce granulation of the parts. Under the most favorable circumstances, hardly any part of the wound can be kept so open by the first intention, the whole is the greater part of a well organized granulation, and the granulation of the edges.—The wound, and the granulation, were then to be formed, and the patient put to bed in a warm room. Finally, the patient was separated, the best application is a wet dressing, which should be put on cold, and it being at the first a source of blood.

Nothing, indeed, is so proper as the dressing, and the dressing is so important as the application, which is the most essential in preventing the granulation of the wound, which is the most dangerous consequence of the description of wounds.

No surgical writer, I think, has given more rational advice respecting treatment to wounds than that permitted by Paganini himself. In general, says he, the treatment of wounded wounds requires that they be simply and slightly, or chlorinated and warm, require the active employment of debilitating means in order to prevent inflammation. Cold water and ice, and general and topical bleeding, are the things usually resorted to with success. Yuccery means, unqualifiedly, and other operations are improper. And if their pernicious effects are not always very evident, it is only because the constant injury has been trifling, and in these nature perfectly easy of cure. In those cases, as well as in those of more serious and glandular, sometimes, death is given in preference to both operations. The internal remedies and vapors (says he) should also be adapted to the condition of the patient. A wound, but, at the end of its course, may come accompanied with a shock and fracture of the bone, while the lacerations have the appearance of being superficial. Such cases are often attended with death, the shock in the soft parts around the bone, which generally supervenes. This is an accident for which immediate amputation is mostly indispensable, even if the wound is not deep, but it may also be capable of preserving inflammation and curement, it is in the active debilitating plan of treatment, assisted with cold applications to the injured part. In such cases, the internal and external use of stimulants is approved of by many surgeons. But Amalut prefers considering the state of the injured limb and the when it is when affected with frost, and he thinks that the employment of stimulants will necessarily produce the same effect as caloric immediately applied to parts diseased with frost. On the contrary, from the active employment of fire and cold in these cases, and in continued injuries is great benefit to the greatest benefit derived.

Amalut observes that there will be need to support the patient. The operation of cold, he says, retards the course of the blood, which, meeting with only damaged vessels, increases the strangulation as it remains in place. By lowering the temperature of the part, cold applications induce distant the danger of inflammation and suppuration, at the same time they have the good effect of reducing the suppuration, which pain from the process that it would be very, in the continuation of blood and violence of the inflammation followed by such applications, and a lowering plan of treatment.

Why, says Amalut, should not this method, which is supposedly adequate to prevent the effects of extension of the brain after blow on the head, be for attaching means employed immediately to extractions and compression of the parts of the body?—Monsieur de Charpignon, (Paris, 1771.) Cold applications, however, in cases of wounded wounds are chiefly to be preferred for the first day or two, in order to check the course of inflammation and suppuration. After this period, I give a divided preference to an emollient liniment, which will be found the most easy during those passages by which the simple one dissolved, the surface of the wound covered, and the state of granulation established. When these changes have happened, the treatment may be directed to the same principles as others in general.—(See Case.)

Punctured Wounds.—A punctured wound signifies one made with a sharp-pointed instrument, the external surface of the injury being small and contracted, the wound being in a line perpendicular to its depth.

A wound produced by the point of a sword or bayonet affords an example of a punctured wound. Wounds of this description are in general, unfortunately more dangerous than any, notwithstanding the latter have the appearance of being by far the least serious. In these cases, the greatest degree of danger always arises from the injury and much violence, which the blow has suffered, in addition to their own division. Many of the dangerous consequences are also to be attributed to the considerable depth to which these wounds extend, whereby important parts and organs are frequently injured. Sometimes the treatment is rendered peculiar by the facility of inducing suppuration and suppuration, as, for instance, a puncture of the vagina which involves the rectum. Lastly, experience proves that punctured wounds and stabs are particularly liable to be followed by a great

deal of inflammation, fever, deep-seated abscesses, &c.

A strange notion seems to prevail, the feelings of many systematic writers, that all the danger and disagreeable consequences of punctured wounds depend entirely upon the narrowness of their orifices, so that suitable applications cannot be introduced to them but. Here, it is already recommended to draw the vessels of every side, with the view, as it generally added, of converting the accident into a simple incised wound. Some of these writers are advocates for making the dilution, with a cutting instrument, while others, with equal liberality, propose to enlarge the opening with tents.

Certain authors regard a punctured wound as a closed injury, and, in order to make the latter surfaces unite, they recommend causing a degree of inflammation in them, either by means of venous or injections.

In the earliest edition of *The First Lines of the Practice of Surgery*, I took particular pains to expose the folly and error which prevail in most writings on this point of practice. In the latest work I have remarked, that if the action were true, that an incised and punctured wound, such as the stab of a bayonet, could be actually changed into a wound pointing out of the skin, instead of an incision, by the mere enlargement of its orifices, the corresponding practice would equally be highly recommendable, however painful. But the fact is otherwise: the rough violence done to the fibres of the body by the *quantity* of stabs is also likely to be suddenly removed by an enlargement of the wound. Not only the distance to which a punctured wound frequently penetrates, and the number and nature of the parts lacerated by it, but all added by such a penetration. These which are the great causes of danger, and of the collection of matter that often takes place in the same under consideration, must exist, whether the mouth and canal of the wound be enlarged or not. The next step, however, we prefer it when there are foreign bodies to be removed, attempts to be opened, or space to be divided. To make partial incisions rather than they can remove, or even incisions and treated. They are sometimes rendered quite unnecessary, by the union of the wound throughout its whole extent without any suppuration at all.

Making a free incision in the early stage of these cases and usually seems a reasonable method of preventing the formation of abscesses, by preventing the collection of matter, and were it not an inevitable consequence of all punctured wounds, for which no incision had been planned at the moment of their occurrence, it would undoubtedly be explicable to some extent. But, however, as time passes away, it is only superficially plastic, and a small degree of infection, even discolors the wound of real solidity. Under what circumstances does it occur? As they are found only where there is some cause existing to prevent the healing of an abscess? This cause may either be the indirect way in which the abscess communicates with the external opening, so that the pus cannot readily escape; or it may be the presence of some foreign body or carious bone; or, finally, it may be an induration of the lower surface of the abscess to form granulations, arising from its long duration, but, however, by laying the abscess completely open to the influence of the air. That is becoming manifest, that the common explanation of punctured wounds is followed by vision only when the common opinion is to procure a free issue for the matter after its accumulation, or when he subjects to make any unnecessary incision. But as either the wound at first can only tend to enlarge the inflammation and render the suppuration more extensive, it might serve to be prejudicial in these cases, except for the direct object of giving freedom to matter already collected, and of being able to remove dangerous bodies properly lodged. I shall now state, repeat, that it is an erroneous idea to suppose the introduction of punctured wounds to prevent a cause of the last species, which they are often intended, that the treatment might eventually be able to be removed.

Recent punctured wounds have scarcely had the same plan of treatment applied to them as old and callosities. Scarce and dissolving injections, which in the latter cases, sometimes act beneficially, by exciting such inflammation as is productive of the effluvia

dies; but if any vein of considerable magnitude be hurt, they quickly design themselves to their labors, knowing that nothing can then be of service. Among the venous anastomoses they chiefly deposit, are serum, red, mamma, and, particularly, strong doses of venous, as will be presently noticed again.

If we put down of coagulation, insulate affected with rubber, the viper inflicts the worst poisoned wound ever met with in these islands. In fact, it is an animal that inserts into the part which it bites a poisonous capsule of exuding very active venomousness. The jaws of the viper are furnished with teeth, two of which in the upper jaw are very different from the rest. These, which are about three lines long, are covered, for about two-thirds of their length, with a transparent coat, or sheath, one of a curved shape, and articulated with the jaw-bone. When the animal is tranquil, and its mouth shut, they lie down with their points turned backwards; but they instantly project forwards when it is irritated and about to bite. In these points which are furnished by a very narrow flange, as their sheath slides, a little way from their point. The rest of these flaps is very hard and solid, and the canal is usually filled with a transparent, yellowish fluid, the poison of the viper.

This venomous fluid is supplied by two glands, or rather by two chambers of glands, one on each side of the head, placed on the front of the forehead, directly behind the eyelids, under the muscle which drives in the upper lip. These the animal cannot get withdrawing from view, and presenting the exterior of the head which they are destined to prepare. A little bag or vesicle, connected to the base of the first part of the appendage, as well as to the end of the second, covers also the point of the curved flaps, and serves as a reservoir for the venom.

The viper is chiefly found in hills, woods, and woody districts, and seldom is hit in many places. It is not its habits to attack man, or large animals, except when provoked. Its venom is easily applied for the destruction of smaller animals, such as mice, frogs, &c., which are usually swallowed whole, and to the digestion of which the venomous secretion is by some writers supposed to contribute. When, however, a viper is provoked, and upon being held up, or hurt, it immediately bites, and, while it only on account of the shape of the flaps, the wound might be attended with very trifling effects; but it is certain of being so, by reason of the species of inflammation which commences it, and of which the mechanism is as follows:

When a viper is about to bite, it opens its mouth very wide. The two curved flaps, which had previously lain flat in the cavity of the mandibles, are affected at their base, and project and become perpendicular to the lower jaw. When the bite taken place, the poison is propelled through the flaps by the contraction of the muscles and the closure of the mouth, and is injected into the wound with a force proportioned to the accidental quantity at the time, and the vigor of the animal.

The bite of a viper is quickly followed by severe effects, some of which are local and the others general, but it is with the former that the disorder invariably commences. At the instant of the bite, the bitten part is swelled with as little pain as when a blow is given over the whole flank, and even affects the system and internal organs. Soon afterwards, the wounded part swells and reddens. Sometimes the inflammation is confined to the circumference of the injury; but most frequently it spreads extensively, quickly affecting every part of the limb and even the trunk itself. A swollen limb is often discharged from the wound, around which phlegmons arise similar to those of a burn. After a short time, however, the pain abates considerably, the inflammatory tension changes into a density or induration softness; the part grows cool; and the skin exhibits large livid spots like those of gangrene. The general symptoms also come on with celerity: one patient is troubled with anxiety, prostration of strength, difficulty of breathing, and cold profuse sweats. Vomiting frequently occurs, and sometimes copious bloody evacuations from the bowels. These symptoms are almost constantly attended with a universal palloriness and extruding pus about the navel.

The effects occur in the same way in nearly all subjects, with some differences depending upon the par-

ticular sensibility and constitution of the patient; the degree low temperature of the atmosphere; the greater or less anger of the viper; the number of its bites; the size of the region itself; the depth to which the flaps have penetrated; and whether the bitten part happens to be one of great sensibility, or was injured at, or the time of the accident. In general, weak, constitutionally persons, of bad constitutions and loaded stomachs, suffer more suddenly and alarming consequences than strong, healthy subjects who view the danger without fear. Several have died, of course, more dangerous than a single one; and, lastly, it has been remarked, that the venom of the viper is more active in summer than the winter.

A year or two ago, however, the newspapers recorded the death of a servant, from the most violent inflammation of the poison to a scratch on his hand, as he was examining the limbs and venous system of a viper perfectly tamed in the winter season.

Severe, however, as the effects of the bite of a viper may be, they are far from being so poisonous as they are commonly supposed to be. Indeed, the viper rarely proves fatal to an adult, even when it is bitten by a viper in the middle of summer, the period when the animal is most active and venomous. Numerous to this common belief, however, are upon record. Thus, in the year 1746, a woman in France, aged sixty-two, was bitten, the flaps of a viper, and died in thirty-seven hours, notwithstanding she internal use of the liquor antivenereum, and the evacuation of the wound and suppuration, even of it with her hand. In this case, it is to be observed, that no other elapsed before any thing was done. — (*See Annuaire de la Société Médicale*, t. 1, p. 40, *des Paris*, 1820.)

Fontana, therefore, was not exactly correct in concluding, that the bite of an ordinary viper will not prove fatal to a full grown animal, nor even to a large dog, though it does so in smaller animals. Five hares from their strong and healthy, were not able to hold a dog's mouth shut for a moment; and as this dog was little more than a third part of the weight of an ordinary man, Fontana supposed that a single bite could never be fatal to an adult. He says, that he had seen a dozen cases himself, and had heard of fifty more, only two of which ended fatally. Concerning one of these cases he could get no information, the other patient perished of gangrene twenty days after the bite. The information about these days after the accident, the bitten place having been deeply scarified, almost has been as the viper was received. Fontana infers, that much of the poison, &c. is lost even upon the bite of a viper, is the more effect of time. "Upon a person being bit by a viper, the fear of its poisonous bite terrifies himself and the whole family. From the perception of the disease being mortal, and that not a moment is to be lost, they apply violent and harmful remedies. The fear increases the complaint. I have known a person that was imperceptibly bit in the back of the foot, and who, after seeing the blood, and observing a viper near him, suddenly started away; over, is particularly observed in a woman for upwards of an hour, until he was accidentally observed and reassured out of it by being suddenly drenched in cold water. We know that death itself may be brought on by the best affluence of the blood, without any internal disease. Why may not people who are bit from a viper be produced solely by fear, and who would not otherwise have died from any complaint produced by the viper?" Although it must be owned that Fontana has been again and again of opinion upon this subject, the above reasoning is hypothetical and incorrect. If it were to be proved, that some very mild, delicate, or nervous people die from fear alone, it would not be admitted, that the generality of people die by broken panic also from the violent effect of animal venom.

Whenever the patient dies, the capsule is always mentioned to the quantity of venom injected in the wound; the number of bites; their situation near important organs; and the nature of proper means of relief. In ordinary cases of a single bite upon the extremities, the patients would not well even without any assistance; but the symptoms would probably be more severe and the cure slower.

From some facts supplied by Sir Everard Home, and observations made on the operation of the poison of the snake-headed scorpion of St. Lucia, the robin of

Capitis, and the calvariaque, it appears, that "the effects of the bite of a venomous reptile according to the intensity of the poison. When the poison is very virulent, the local inflammation is so rapid and so violent, and its effects on the general system are so great, that death soon takes place. When the body is otherwise unprotected, the daily absorption of venous matter with it in the parts close to the bite, where the cellular membrane is completely destroyed, and the neighbouring vessels very considerably inflamed. When the poison takes longer to spread to the general system does not prove fatal. It keeps on a slight degree of absorption, and the part in the part takes in very slowly; in about half an hour, swelling takes place from an effusion of serum in the cellular membrane, which continues to increase, with greater or less rapidity, for about twelve hours, extending during that period over the neighbourhood of the bite. The blood seems to flow in the small vessels of the vascular parts; the skin over them becomes quite cold; the action of the heart is so weak that the pulse is scarcely perceptible, and the stomach is so irritable that nothing is retained by it. In about sixty hours, these symptoms go off; inflammation and suppuration take place in the injured parts; and when the abscess formed is very great, it proves fatal. When the bite has been in the finger, that part has usually healed. When death has taken place under such circumstances, the abdominal vessels and their glands have undergone no change whatever in the effects of the morbid poison, nor has any part lost its natural appearance, except those immediately contiguous with the abscess. In those patients who recover with difficulty from the bite, the symptoms produced by it go off more readily and more completely than those produced by a mortal poison, which has been received into the system."—*Sir R. Hardy, Case of a Man who died in consequence of the Bite of a Rattlesnake, in Phil. Trans. 1841.*

[There is scarcely to be found a more interesting case of the kind than that recorded by Sir Richard Brown, as quoted by our author, and the history of the case deserves to be read with all the care which Sir Richard has given to it. No other question than the intellectual power of the patient were materially affected. This is an unusual circumstance only in cases of poisoning from venoms and poisons. Sir Brown appears to have been the father in the case of a young man, Mr. A. of New-York, who was in 1811 seriously injured in the arm by a rattlesnake; that and been kept in confinement three years. The wound of the poison, according to Dr. Paracelsus, began to exert its effects in the formation of Suppurative Abscess, upon the first hour, and in local cancrum, such as went under the name, *St. Ignace's Abscess*. But in the case of A. the mind preserved its wonted functions throughout the whole disease. When the bite is inflicted in a large vein, its effects were to be local, permanent, and its duration more certain than under other circumstances.—*See Fagge's Med. Jurisprudence, New-York Med. and Phys. Journal, vol. V. No. 1.*

Nostrum remedies for the local action of the venom have almost entirely failed. According to certain writers, each of these remedies has effected wonderful cures; and yet, as Boyer well remarks, every one of them has been in its turn, relinquished for another, the sole recommendation of which has frequently consisted in its virulence. Any of these boasted specifics, though of opposite qualities, as it were, seemed to cure the patients, and the possibility of such a cure led him to try the next, until he was at length cured, when the patient, or when he administered it year after year, recovered perfectly after suffering a train of severe symptoms. But the reason of this pretended efficacy becomes obvious, when we know that the bite of a viper is of itself rarely mortal to the human subject, and that the severity of the symptoms materially depends upon the quantity of the venom in the wound.—*(Boyer, Traité des Maladies Chir. &c. t. 1, p. 428.)*

The treatment of the bite of a viper is divided into local and general system.

The local treatment has for its principal object the destruction of the venom, the prevention of its entrance into the vessels of the neighborhood of the wound.

Of destroying the wound, I shall only say that it

prevails on utility, if it is practised with care of drying each dressing is applied at very short intervals. For many know that the surface of the wound is not in this manner. Potent was an attempt to apply ligatures round the limb in order to arrest the progress of the venom into the circulation, and it thought that by such means much might be gained.—*See Second Essay, &c. &c. of system, &c.*

The only rational local treatment in terms of secondary mischief, is making incisions above the wound, to suppress the cellular membrane, and to bleed to the swelling, which only spreads in the parts under the skin, and swelling, for the parts already swelling, that the effect of the venom on the system be dissipated as soon as it is formed. In nature (he says) we employed in America, but with different view, &c. to prevent the poison being introduced into the system.—*Phil. Trans. for 1841, p. 1.* Actual incision, if accompanied by ligatures, should be regarded as not so much as that of the patient himself by the interruption of the circulation. With respect to the application of powerful means, the best of them from that adopted by the foregoing writer, as well be presently noticed.

Section of the wound has been proposed, and some have in be supported by those who express, as I shall presently explain in showing the rationality of section of Dr. Barry.

One of the most certain methods of removing the virus consists in the excision of the bitten part. The operation, however, would hardly be proper, were it not immediately after the injury, when such a dissection had taken place. It is known a person in which such patients would not stand, and even some surgeons might deem that procedure too late, in section in the late of the case of this country. But the benefit also be incrementally caused by the section of the parts. Excision, as Dr. Barry thinks, is only to be used in proportion to its extent. It is not beyond the point of the incision, save, for the skin, and the other parts of the body, which are being now exposed to the atmosphere, and the possibility of poison beyond the boundary of the wound, will pass with increased rapidity to the heart.—*(See Phil. Trans. for 1841, p. 123.)*

Another plan, more cautiously proposed, is that of destroying the venous part with some sort of local caustic. When this is done to use it is said that the poison will be prevented from flowing in further down the system. The caustic itself, it is supposed, may also have the effect of destroying the vessels itself, while they are in motion, and passing into the circulation, instead of being at rest, the neighbouring absorbent system. The venom, which Potbury proposed as a poison, but, as I have already remarked, every cause of suppuration will infinitely have the same effect, as a caustic, in the form of destroying the point of infection, &c. &c. of the venom. In France, liquid caustics are preferred, the fluid mixture of antimony, the acid of arsenic, or the sulphuric acid, being the most common is a dilution, and they have commonly smooth the bottom of the wound.—*(Phil. Trans. for 1841, p. 123.)* Either of these liquids may be applied by means of a slender pointed rod of wood, which is dipped in it, and then introduced into the wound made by the fangs of the viper. The plan is not to be withdrawn, but once, twice, and then again. If a drop of the caustic can be forced in touch the better. When the bite is superficial, and deep, the caustic cannot well be introduced more than a depth of the wound is somewhat satisfied with a finger. A little bit of fat may then be used to cover the above fluids, and be pressed deeply into the wound. The agent and potential caustic, this caustic will only succeed, when their action extends beyond the limits of the poison.

After the caustic has produced its effect, the best application is an emollient position.

It is not, however, every kind of a viper that requires local treatment, even of this degree of severity. When the wound is superficial, the skin is not much affected, the poison is considerably exhausted by its being previously killed, and the swelling is not dangerous; and the patient neither suffers from the effects of the poison, nor from the caustic.

applied; others, however, still, a fluid we must administer, such as the strongest astringent liquor, while others, on the contrary, tried every different kind of medicine. In short, there is hardly any account of medicine that has not been tried on a case in this disease; while at the same time it is known, that, under all the varieties of application, none of the patients died." Hence, Pereira concluded that none of the remedies had any effect in curing the disease.

Later observations, however, led to more and more, that a cure was to be known, which could exempt to persons considerable anxiety, and all the time of a very considerable kind of attack. From some facts recorded in Dr. Ross's History of Indian Diseases, on the authorities of Mr. Duffin and Mr. Rennie, it appears that the Tawjee (it, of which disease is the chief ingredient, is combined with considerable success in India after the loss of enormous perspiration. This information led Mr. Chevreign to propose the fair trial of arsenic.

Mr. Ireland, surgeon to the 60th regiment, had formerly treated Mr. Chevreign's numerous the trial of arsenic, and he was resolved to make the experiment whenever an opportunity offered. On his arrival to the island of St. Lucia, he was informed that an officer and several men belonging to the 60th regiment had died from the bites of serpents, supposed to be the various varieties of Laticia.

The reader will find some interesting account of the serpent here alluded to, in a tract which I have lately read, entitled *Monographie des Tergentophores des Antilles, ou Histoire Naturelle de la Laticia, de la Mamba, de la Vipere, de la Cobra, et de la Serpente de l'Inde*, Paris, 1830.

Mr. Ireland described that every thing had been tried by the attending medical men to no purpose, as all the patients had died, some in 24, and others in about twelve hours from their receiving the wound.

A man, however, soon came under Mr. Ireland's care, who, as nothing else had been done before seemed to have been of any service, he was determined to give arsenic a fair trial.

Jacobus, a soldier in the York light infantry regiment, was bitten in the left hand, and the middle finger was so much lacerated, that I found it necessary to amputate immediately at the joint with the rectus carpi bone.

Just half an hour after, another soldier had received the wound, and found him in a fatal, senseless state. The hand, arm, and breast of the soldier were much swelled, and of a dark purple and livid colour. He was vomiting, and expressed as if much distressed. Pulse quick and hard; he felt little or no pain during the operation.

The wound being dressed and the patient given to bed, I ordered a cathartic, (castor), and the following trochiscs to be taken immediately. R. Lapis, scrupulis ij. Trich. ros. et. l. ʒij. each, sig. 3 iij. which was added to four ounces of lemon juice, and as it produced a slight emetic effect, it was given in that state. This continued for the evening, and was repeated every half hour for four successive hours. In the night, the patient was somewhat relieved with some antispasmodics, and ordered with a balsam composed of Oil of Clove, ʒss. Liqueur anisees, ʒss. and Oil rose, ʒss. The cathartic effect was repeated twice, when the patient began to be purged, and the antispasmodic effect was more discovered. He felt some relief when treated, and from that time he gradually recovered his faculties; he took some refreshment, and had several hours sleep.

The next day he appeared very weak and fatigued; the inflammation and tumour were repeated. The swelling subsided gradually; the natural colour and feeling returned, and by proper dressings to the wound, and attention to the state of his bowels, he soon recovered and returned to his duty.

Mr. Ireland states about four other examples, in which arsenic was exhibited with similar success.

In several particular notes, the report was employed by Dr. Ireland was proposed according to Dr. Fother's description, which directs six grains of arsenic, and as many of the finest vegetable alkali as he dissolved in a small bowl, and the solution to be made an emulsion, so that two drachms contain one grain of arsenic in solution. (See Med. Clin. Trans. vol. 2, p. 300, &c.) Whichever may be the true medicinal treatment of poisoned wounds, the local

management of them on their first occurrence, according to the principles explained by Dr. Hall, are already evident in this article, which seems to be justified, as it is certainly more deserving of commendation, as it operates as a preventive of suppuration, which, and they have come on, sometimes prove fatal. It has been stated that it is too often proved.

A singular case of poisoned wound from the bite of a catoblepas occurred some years since, under the observation of Dr. S. T. Barnard, in Williamsburgh, Pennsylvania, and in some respects is perfectly singular.

A lady in the fourth or fifth month of her pregnancy was bitten by a catoblepas, but under the treatment resorted to at length recovered from the symptoms usually consequent upon such wounds. At the period of gestation, she was slightly distressed by a healthy-looking child; but subsequently on its being applied to the leg and arm, it was found that the wound had produced the most violent effects, and soon died. She then produced a puppy to relieve her limbs, with a few days of the same symptoms. A lamb was then sent, and it succeeded, her puppy, and three lambs shared the same fate. Another puppy was then produced, which suffered with its life, but exhibited no signs of the same wound had been fatal to its predecessor. The lady recovered all this time without any symptoms of disease, and had in rapid a recovery from pain, thus it is really singular.

The poison seems to have been caused by the poison of venereal; for the second girl attacked did not suffer much, and though she suffered a great deal, yet without fearful consequences, in some consequences escaped.

The discovery in which the action of poison is by human copulation is justified, in so far as it is proved when we consider that both of the most common hydrophobia may be produced by a human bite, and that the disease may sometimes be transmitted. According to M. Dumas, in 1827, in an village of Dec, thirty-two persons died, who have been known by mad dogs; and on the next day, hydrophobia occurred in several individuals within three days. (See Journal des Progrès, quoted in Med. et Med. and Surg. Journ. vol. 6.) The cause was not known, but hydrophobia is a disease which is common to the mind, person, foot, face, eyes, the throat, head, &c. Drs. Huxham and Francis explain the opportunity of transmitting a case of hydrophobia. A regular young man, and father of a family, (the father of the late of a child) died. He had been severely injured by his guardian's servant, he was severely affected; the wound of foot and arm, and in the evening, the wound of the foot was about to be broken open by an existing case of his complaint. The symptoms of hydrophobia throughout were similar to those which have been noticed by the bite of a mad dog. (See Med. and Surg. Journ. vol. 2.) A second case in the various means employed for the cure of hydrophobia by Dr. Meade, may be seen in the Med. and Surg. Journ. and through I hope no confusion is so remedy, I must refer to Dr. Meade's paper in the Medical Repository of New York, containing the report of the medical staff in such cases. (See latter Transactions on Hydrophobia.)—Gore.

Wound of the Throat.—The throat is a cavity in an irregular oval figure, bounded in front by the larynx, laterally by the ribs, posteriorly by the vertebrae of the neck, above by the maxilla, and below by the diaphragm, a very powerful muscle, which comes into of position between the cavity of the throat and the inferior abdomen.

The diaphragm is not stretched across to a direct direction from one side of the chest to the other, but on the contrary, descends inarch thereby to some part of the others. If the cavity of the chest be divided by a transverse section, about the middle of the sternum, the diaphragm appears, in appearance, to be very prominent and convex towards the chest, when it is fully distended, and its edges, towards the lower to which the muscle is attached. At the same time, and under elevated gas, it is fixed to the posterior convex surface, descending obliquely to the right and left, it is fixed on both sides to the seventh rib at the lower ribs, and lastly into the lower dorsal vertebrae. According to this description, it is evident that the diaphragm

of the thorax has much greater depth and capacity looking than in front, in circumstances which suggest ought to be well aware of, or the they will be liable to give most erroneous opinions concerning wounds of the chest. For instance, a practitioner deficient in anatomical knowledge might imagine, that a weapon pointed from above downwards into the front of the chest could never reach the lungs, after having penetrated the cavity of the abdomen. It is a fact, however, that no instrument could pass in this direction, even downwards below the highest part of the abdominal cavity, without entering the chest.

The whole cavity of the thorax is lined with a membrane named the *pneum*, which is very adherent to the chest, which lines the parietes of this cavity, and is the *diaphragm*. Each side of the thorax has a distinct pleura. The two membranes meet in the middle of the chest, and extend from the sternum to the vertebrae. In this manner, two cavities are formed, which are in contact with each other. By the two pleurae meeting and lying upon each other, a middle partition is formed, called the *mediastinum*. These two membranes are so situated as to be in contact with each other, the whole length of the sternum; but behind, where they approach the vertebrae, they separate from each other, so as to leave room for the *aorta*, *oesophagus*, &c. The heart, enclosed in the *pericardium*, occupies a considerable space on the left of the *mediastinum*, and all the rest of the chest is filled with the lungs, except behind, where the large blood-vessels, *aorta*, *oesophagus*, &c., and *oesophagus* are situated. In the perfectly healthy state, the lungs do not adhere to the pleura; but in the majority of subjects, at least in this climate, when they are examined after death, such adhesions are found to a greater or less degree. The thoracic cavity probably is not covered by any slight inflammation; and as the surface of the lungs is naturally covered by an air, in close contact with the pleura, and patients are frequently not supposed to have any thing wrong in the chest, this essential change being often accidentally discovered after death, is looked for something else, it may be concluded that it does not produce any serious effects.

The thorax is subject to all kinds of wounds; but their importance particularly depends on their depth. Those which do not reach beyond the integuments, do not suffer from serious wounds, and when properly treated are seldom followed by any bad consequences. On the contrary, those which penetrate the cavity of the chest, even by the slightest opening, may give rise to alarming symptoms. Lastly, wounds involving any of the thoracic viscera are always to be considered as placing the patient in a state of considerable danger.

First what has been said, it appears that wounds of the thorax are very properly divisible into three kinds: 1. Such as affect only the skin and muscles; 2. Such as enter the cavity of the chest, but injure none of the viscera; 3. Others which injure the lungs or some other viscera.

Superficial Wounds of the Thorax.—Immediately a weapon is called to a wound wound of the chest, the first duty should be to ascertain whether the weapon has penetrated the pleura or not. In order to do this judgment on this important subject, the following are recommended: 1. Placing the wounded person in the most painful position, as when he is inclined the wound, and then carefully examining, with the finger or probe, the direction and depth of the stab. 2. The symptoms, if positive, of the weapon, as in most cases each of it is entered with blood. 3. The lightness of fluid into the wound, and attention to whether it immediately increases or subsides in the part. 4. The colour and quantity of the blood discharged from the wound are to be noticed, and whether any is coughed up. 5. We are to ascertain whether air escapes from the wound in expiration, and whether there is any employment. 6. Lastly, the state of the pulse and breathing must be ascertained.

In wounds of the chest, however, surgeons should not be too cautious with their probes, merely for the sake of gratifying their curiosity, or attempting to be doing something. No judicious surgeon can doubt that authors have dwelt too much on the subject of probing wounds of the abdomen and thorax; for they would really lead their readers to believe, that the wound has been treated with the finger or probe so to vary between and over-treatment, surgeons are not qualified to

institute any mode of treatment. The only advantage of knowing that a wound penetrates the chest is, that the practitioner immediately feels himself justified in doing recourse to bleeding and other antiphlogistic means, with the view of preventing inflammation of the pleura and lungs, which affection, if not cured in time, often proves fatal. However, there can be little doubt, that if the nature and depth of the wound cannot be readily ascertained with the eye, the finger or a probe, or by the discharge of air or blood, it is much safer to live ignorant than to put him to useless pain with the probe, and waste opportunities of doing good which too frequently can never be recalled. In short, generally speaking, it is better and more advantageous for all patients, that some of them should lose blood, rather than that any of them should die in consequence of the evacuation being omitted or delayed.

Almost all writers, who have taken pains to direct how wounds of the thorax should be treated, conclude with remarking, that however advantageous a knowledge of the direction and depth of the wound may be, such hints have frequently been done by pushing the attempts to gain such information too far. It is, perhaps of greater importance to learn by some kind of estimation, the extent of a wound, which does not reach beyond the *mediastinum* or *intestines*, than to know whether the wound extends into the cavity of the chest. For even when the pleura is found to be divided, if the wound be covered with an *aspirator* or *aspirator*, the information is of no practical use, if we make it a custom to adopt, without the least delay, a strict antiphlogistic plan of treatment in all cases, in which there is any suspicion or chance of the path within the chest being increased and likely to inflame. Besides, frequently the symptoms are more urgent and alarming, than they could be, were only pain on the inside of the chest injured; and under such circumstances, it is needless that a probe should be necessary for determining that the wound extends into the chest.

With respect to the injection of lukewarm water, or any other fluid, and the circumstance of its respiration as a reflection of the wound being only superficial, the plan is more objectionable than the employment of a probe; for if the liquid be propelled with force, it may be injured into the pleural substance, and even to be passing through the track of the wound into the chest, while, in reality, not a drop does enter. Besides, it is a wretched proceeding to try to unite any quantity or kind of liquid whatever between the pleura and lungs, into a situation in which it must necessarily obstruct the important function of inspiration, and cause serious inconvenience.

When air issues from the wound in expiration, there is ground for suspecting that the lungs are wounded. But I believe that such signs at present this circumstance as an infallible criterion of the nature of the wound, labour under a mistake; for when there is simply an opening in the chest, without any injury of the lungs whatever, the same symptom may occur. The air which is discharged through the wound in expiration has previously entered the bag of the pleura through the same wound in inspiration. In order to remove all doubt, the patient may be requested to expire strongly at his ease, so as to know whether the air has accumulated in the chest. At the end of each expiration of this kind, care must be taken to bring the skin closely over the orifice of the wound, and to keep it thus applied during each following inspiration, for the purpose of preventing the entrance of air from without. In this way, if there is no wound of the lungs, all the air will soon be expelled; but if it still continues to be discharged in expiration, the lungs must be wounded.

Sometimes an inflammation swelling takes place round wounds of the thorax, in consequence of a quantity of air diffusing lower in the cellular substance. In wounds which are slight and single this swelling is very uncommon, but in cases of narrow oblique stabs, and where the lungs are wounded by the points of broken ribs, it is by no means uncommon. (See *Emphysema*.) When a considerable quantity of blood flows from the wound, there is reason for conjecturing not only that the weapon has penetrated the cavity of the thorax, but that some of the thoracic viscera are injured. Excepting the *aorta*, which runs along the edge of the lower ribs, and the trunks of the

When the nose is pushed pointed toward the floor of the divided parts are too supply on, they are also considerably stretched, heated, and when very irritated, bleeding profusely. They will not smother of being excited so readily as the sides of a throat, and, hence, require a sharp stimulant. However, the possibility of getting the opposite sides of punctured wounds must depend very much on the character of the weapons, and the calmness, firmness, and absolute truth which it has driven into the part. A quick with a needle is a guaranteed remedy on the first made by surprise, with their failure; yet these injuries do not frequently bring on inflammation and abscesses, as other wounds frequently do, which are inflicted with bayonets and knives.

Little is known of the man who received the thrust of a bayonet, which fell into the sea, and swayed, carrying one side of the line, to the point that the sailors looked with the greatest advantage at his father's.

Instead of laying open the whole track of such a wound, with a knife, as is unfortunately recommended in many of the books on surgery; or instead of drawing a suture through the whole course, or of 40 stitching over the part a hard irritating cast; the practitioner should take temporary closure there may be of saving the wound without suppuration. For this purpose, he should remember that the great danger of violence done to the parts is placed there is the reason why they are so easy to inflame and suppurate. Hence, the expected inflammation is to be concentrated in delivery first instance; and immediately the wound is closed, the patient should be bled 100, and afterwards take purgative medicines. With respect to the dressing, the orifice of the wound may be lightly closed with sticking plaster, or covered with a cold superficial application. Once and several times the wound may be kept open, kept constantly wet with cool water or the liquor plumbi acetate distill. As, however, many patients have a strong dislike to any application to very wounds upon their bodies, it is often necessary to dispense with this method. The dressing can so be retained with a roller; but it is not to be again necessary to have likely to do water than good. Thus, the inflammation of the wound will be subdued; the extravasation of blood preserving the chance of union by the first coagulum when; and all partial operations avoided. And nothing is more certain than the fact that if an abscess opens, it is rarely cured, many times just without suppuration, or may very soon suppurate, when no hope could be entertained of these things, or under other treatment. But if suppuration should happen, and a discharge of matter take place, would the patient suffer more or longer than if the wound by having a proper dressing, and of just sufficient size, were made into the abscess than a simple plaster, that it be not subjected to have the formidable operation of laying open the whole extent of a such perforation in the first instance. In short, will be sufficient to avoid, be laid off just in getting well, or have to give rise into the danger? With still more advantage, by with the taking a regular course in which methods all these causes the wound would not avoid by what it should be the best treatment, and to try, without any suppuration. I need not enlarge upon this subject, but refer the reader to what has been said in the preceding remarks on the subject of Pustular Plague, and in the treatment of abscesses, to the above suppuration. Goodwin would hereby asking the purpose of the chest are to be removed according to principles already explained—(see General Remarks.)

Of *Hawaii protesting the closing of the Thorpe*.—
 "Favorable measures" for that big *Hawaii* corporation,
 and thus the famous situation of the postmaster. I
 want not only to see, but also to see the story of
 Thorpe, but without losing the value.

Another highly sensitive and important study by the FBI in 1981, titled "Investigation and Control of the Gangs in Chicago," was the first to attempt to identify the structure of the gangs in Chicago and to develop a classification system for the gangs. The study found that the gangs in Chicago were organized into a hierarchy, with the most powerful gangs at the top and the least powerful at the bottom. The study also found that the gangs in Chicago were involved in a variety of criminal activities, including drug trafficking, prostitution, and gambling.

of the larynx. If one of the intercostal arteries be wounded, and the external surface be very painful, the blood, furnished by this vessel, may pass into the chest, and immediately produce asphyxia of the breathing, and other symptoms of pressure on the lungs. Of what is to be done in this case, I shall presently treat.

[illegible]

Perforating wounds of the chest are accompanied with signs of the following circumstances: 1. Foreign bodies. 2. Injury of one of the intercostal arteries. 3. Penetration of a portion of the lungs. 4. Emphysema. 5. Reabsorption of blood in the thorax.

2. About 1/3 these wounds occurred just and directly at localities. Many of them are also followed by an equally serious swelling around the wound; the patient frequently swells all about; and after having laid for some time a small, constrained, irregular patch, with a small macerated and red center, he is the often victim with severe edema, sometimes, the effect of inflammation of the lungs and pneumonia the cause. These symptoms almost invariably follow the bleeding, a very low rigors, a pulse like tremulous, the use of leeches, or support, and the other treatment of aneurism. If much blood is poured out, recovery longer than a few days without treatment, unless before it that there is ground for supposing that they depend upon the position of some foreign body. However, it may be feared whether Soliman's advice, to continually rub with such a soft, warm, and moist substance, is proper, after these hemorrhages. For my own part, I cannot think the pyrexia also notified by an acute aneurism, and even were it so, on the principle above it will be removable.—*See Medice Quæstio, p. 20.*

Butcher inquired of the men following cases, for the purpose of showing what really be attempted in these cases. "A man, twenty-seven years of age, was struck very suddenly, and a knife on the outer part of the fourth rib rose. Simple dressings were applied for the first four days; but a considerable swelling and splitting of blood staining, Mr. Gillet was consulted, who found that the symptoms depended on the presence of a piece of the knife, which had passed the rib and was protruding some six inches from it. The title of the foreign body was on the inside of the rib, and it was so fixed in the bone, that it could neither be connected with any kind of forceps nor even moved in the bone with a bone saw, Mr. A. Although the only standard seemed to be that of saving or removing a portion of the rib, Gillet conceived, that in at least, might be made to extract the foreign body by pulling it from within outward. For this purpose, having put a good thick cloth under finger, he introduced it into the cavity of the thorax, and thus succeeded in pushing up the piece of the knife.

A speech of the house was intended, but it was too firmly connected with the rest of the visit to admit of being emphatically taken off. General was allowed enough to surround the whole with an artificial guard with a bayonet. This is a serious proceeding, as the French were then engaged, but only the examination of all the final operations, but a speedy recovery. — (See Dr. Page's *Nile to the Third Air Operations in Egypt*.)

A reflector was shot in the left side of the chest. The bullet penetrated between the lower end of cartilage of the seventh rib (11 ribs), and came out in the situation of the upper end of the same bone, which was broken in two places. The greater part of the first lobe of lung was destroyed. Immense blood clots which filled the cavity, to take away several volumes of blood, and contained thin needles. Freshly granular fat.

When the wound corresponding to the intercostal artery was sufficiently exposed in the transverse direction, the narrow, distal end of the instrument was introduced, that the lower edge of the rib might be placed in the convexity of the curve, which the compressor acted on the edge of the bone, and, of course, on the artery. The rest of the instrument applied itself in the side of the thorax, in which situation it was retained. When the wound was not deep enough, a sufficient isolation of it was that made for the introduction of the instrument.

Quercy employed a piece of ivory, which he covered with lint, &c. and introduced it into the chest. The instrument was then, for a few minutes, retained externally by means of a thread, and then the necessary compression was produced.

Quercy's plan is somewhat like that favoured by Jany, but he has introduced the compressor entirely into the thorax, together with the ligature, which was the basis of it, and he has to have drawn the compressor from within upwards, he was probably intended, a very large wound would have been indispensable. This was also one of the many strong objections to Jany's instrument, which, in fact, could only be employed when there was a free and ample opening.

Billroth, seeing the inefficiency of all the compressing means used before his time, and such compressors, invented an instrument, which he only calculated for making private pressure, and following the motion of the chest without interfering the escape of extravasated blood. The machine is represented as described in *U. of Mass. v. 1, vol. 41, Ch. 40*. It is composed of two plates, which are added, and capable of being brought towards each other by means of a screw. This instrument, as Billroth observes, may indeed answer; but it is complicated and awkward, and its utility is founded on the supposition of the wound being larger than wounds are which are made with common weapons.

Justly seems to any unnecessary multiplication of medical instruments, modern practitioners regard all particular contrivances for stopping haemorrhage from the intercostal arteries. Indeed, as the archipel is very rare, it is probable, that the best instrument possible were devised it would hardly ever be at hand when required.

A common kind of flat (says Billroth), directed to a strong ligature, and introduced between the two ribs, or even quite into the chest, and then drawn back within towards the Quercy's compressor, would fulfil every desirable purpose. The external wound should then be covered with simple dressings, and a bandage applied round the body. The patient should be freely and copiously bled, and treated on the most rigorous antiphlogistic plan.

Professor Acland joins all the best modern surgeons in recommending the introduction of the preceding compressors and various substances into the chest, in order to stop haemorrhage from the intercostal artery. All these methods, he remarks, are calculated to excite a dangerous degree of inflammation in the chest. Hence, he prefers simply cutting the artery across, so as to show it to retract, and, if this plan fail, he recommends the wound to be closed. Should the blood find passage into the chest, it is true the compression would be useless, but not fatal; and if the symptoms require it, the operation of resection may afterwards be done. A small quantity of dried blood, however, may be absorbed, and no such complaint is dangerous. — *Manual of Chirurgie*, p. 26, 30.

Dr. Wilson observes, that whenever the thorax has been opened for an internal intercostal artery, the practice should be adopted. He states, that when he reported in which the vessel was thus secured, but that he has never seen the method adopted himself. "The fact," he says, "is, we but the vessel and the patient in finding the source of the haemorrhage, and here probability is not only means. In some very slight cases, I have used the compressed compressors in the thorax; but if the bleeding is excessive, seeing that the fibres of an artery, referred to often as arteries may require, and pressure direct upon a compressor placed along the course of the vessel, or as depend on temporary compression, which is of any avail?" — *Medical Surgery*, vol. 3, p. 275.

2. The protrusion of a portion of the lungs, in con-

sequence of wounds penetrating the chest, is a very unusual case; but there are some instances recorded by writers, and one time I attended myself after the battle of Waterloo. Schenkling relates an example taken from Robinson. The latter was called to a man who had been wounded in the thorax six days before. A portion of the lung protruded, in a state of excitation. Robinson extracted it, and the patient soon recovered.

Taylor also reported a similar fact. A man received an extensive wound just below the last rib. His external gas disposition, however, led him to neglect the injury; and on the third day, a piece of the lungs, three inches in length, protruded. The patient went to Amsterdam, whence he was taken two days' journey, for the purpose of receiving succour in one of the hospitals there. The protruded piece of lung, which was avulsed, was dried, and set off with saltpetre. It weighed three ounces. The wound healed in a fortnight, and the patient experienced no complaint afterwards, except a slight cough, with which he was occasionally troubled. He survived the accident six years, leading a wandering, drunken life. After death, nothing particular was observed in the thorax, except that the lungs had become adherent to the pleura, at the situation of the wound. Billroth relates another case. A man was wounded with a knife between the fifth and sixth ribs, near the sternum. As a piece of lung protruded at the opening and was of a dark colour, it was extracted with the actual cautery. The wound was then closed, and the ribs kept apart with a wooden wedge, under which was the portion of lung left by the opening struck within the chest. The patient was soon completely well.

A fourth example of a protrusion of a piece of lung through a wound in the thorax, is among the cases recorded by Baylis. The extent of a swelling was wounded in the anterior and inferior part of the chest, and was apparently, attended by a rupture, when indeed the protruded piece of lung for a portion of column, and applied a tight ligature round it. Baylis, who was consulted, soon detected the mistake which had been made, but he desisted his opinion that the wound would heal very well, as soon as the tied piece of lung was detached. The event justified his prognosis, and the patient recovered.

When the protruded portion of lung is small, the redundant ought to be made without the least delay. It should be done on the same principle as those on which protruded pieces of intestine, or omentum, are retained—*vide* *History of the Abdomen*. A recurrence of the accident is to be prevented by closing the wound, and placing a compress over it. But when the piece of lung is already in a mortified state in consequence of the constriction which it has suffered, or when its large size prevents reduction, Sabatier is of opinion that the only resource is to cut off the part, after applying a figure round its base. If the latter step were not taken, a dangerous haemorrhage might follow, or even an extravasation in the thorax. — *Medical Operations*, tom. 2, p. 204. However, the practice recommended by Sabatier appears questionable in the instance of mortification, because the dead part will naturally be thrown off by a spontaneous process; and when the wound is too small to allow the part to be retained, its resection might be more advisable than the removal of a considerable portion, or even any of the lung.

After the battle of Waterloo, I had a patient with a penetration of a piece of lung, to five inches in length. The part was much burned, and could not be easily reduced. I therefore applied a ligature round its base, and cut it off. Previously, however, I made an incision in it, in order to ascertain whether it would bleed freely, which being the case, induced me to use a ligature. I was afterwards informed by my friend, Mr. Collet, that the man died.

3. Empyema is another symptom with which penetrating wounds of the chest are frequently complicated, especially when they are small and indirect. When such wounds are small, and not directed to their source, when their track is undisturbed by other things, by change in the situation of the patient, the swelling of the parts, state of blood, or any numerous obstructions, we may mistake them for the cellular substance, so as to cause a great deal of mischief and dis-

however, the patient, in making an effort to expire, emitted the *stridor*, the air exhaled in the lungs of the wound was only in proportion to the amount of air and vessels of the lungs, on the same side as the wound, so as to distend them, and even cause them protrude in the wound.

Dr. Halliday remarks, that such a protrusion often happens when wounds are made in dogs, and has been erroneously noticed in an argument against the escape of the lungs when an opening is made into the chest of the human subject.—(See *Obs.* on *Emphysema*, by Dr. J. Halliday, 1855.)

For information concerning the treatment of this affluence, see *Emphysema*.

I have already noticed, that wounds of the thorax may injure one of the vascular arteries, and when the blood cannot flow away it may be extravasated in the chest. This extravasation may delay the escape of the pulmonary vessels, those of the lungs, or of the heart itself. And here I may take the opportunity of remarking, that extraneous wounds of the lungs do not prove immediately fatal. A vessel, in which a *bullet* passed through the lower, lower, diaphragm, part of the lungs, and the right ventricle of the heart, and yet the patient lived nine hours after the nature of the injury, is recorded by Dr. Richardson.—(See *Not. Morgagni and Richardson*, *Lancet*, 1789; also a case by Chesnut, in *Journal de Med.* 1812, t. 2.) In almost all cases, however, such injuries prove instantly fatal; and the same remark will extend to cases of hemorrhage from vessels above a certain size, but in these they are less considerable, the patient may live for a greater or less time, and before the aid of surgery.

[Though wounds of the heart are deemed extremely fatal, they do not always immediately prove so. Our medical records contain various cases in proof of this, very recently a case of murder came before the Criminal Court of New-York, in which the medical witnesses in behalf of the people advised, that the deceased, as proved upon the extramurder of one body, had received the fatal wound in the left ventricle of the heart; yet the sufferer survived nearly three quarters of an hour after the occurrence.—*ibid.*]

The following are the symptoms which denote an extravasation of blood in the thorax. The person feels great oppression, and soon complains as will not let him lie in any position. Unless his head has been very much lowered, in which position the diaphragm is relaxed, and not so much distended by the weight of the extravasated fluid, the first point of difficulty is standing or sitting up. When the rigidity is less, the patient can be with tolerable ease on his back; he is also not averse to lying on the side on which the wound is directed; but he cannot place himself on the opposite side without feeling very acute pain in the direction of the extravasation.

His respiration is short, frequent, and interrupted by sighs; his voice is hoarse; a colorless pale skin spreads over his countenance; his extremities become cold; a violent perspiration covers his neck and temples; his heart ceases; his pulse becomes weak; and if, as most frequently happens, the lungs are wounded, he coughs up frothy blood, and air issues from the wound.

Though one might suppose the above state of symptoms always attended as a considerable effusion of blood in the thorax, this is not the case. Wounded persons have been known to die of such an extravasation when symptoms were scarcely seen, and who did not complain of difficulty some hours before in any position that they assumed. Scudder says, that several times of late he has found bodies in the chest discovered. These wounded persons show when confined some of the symptoms attributable to extravasation of blood in the thorax, have been unable to sit up, vomit, have great oppression of a purple color, attended by a violent and superior pain of the chest, about two inches of the sternum, the ribs stiff, difficulty of breathing, and have been seen to expire, and as the symptoms were supposed to exist, not many were thinking of making an incision for its evacuation. A patient was one evening present, exhibiting rather the last of Emphysema, and last of emphysema, made him almost insensible. He became more composed by treatment, and the application of leeches, though at a distance of some of the wound.

However, even the assumption of the above symptoms did not direct Parr. Having been impeded to

point of an operation which was about to be done on a wounded man, about whose aspect, prostration, and, and numerous other vessels, a promiscuous emphysema was existing and taken place; whose respiration was painful and difficult; and who spit up frothy blood. Parr gave it as his opinion, that it was unnecessary to make an opening into the chest. He thought it would be sufficient to enlarge the wound, which was at a little distance from the sternum, near the edge of the fifth rib, and so as to give vent to the effluence of air. This advice was followed, the emphysema soon subsided, and the patient recovered.

The malignant nature of the symptoms of extraneous effusion of blood in the thorax, has induced physicians to pay the most scrupulous attention to every circumstance attended on these cases. In several instances, Valentin remarked, that an erythema occurred in the angle of the ribs, and had spread towards the heart. The erythema is described as being of a clear purple color, like the spots which sometimes form on the abdomen a little while after death. In a case, in which each of the symptoms of extravasation were combined with the above sort of erythema, Valentin advised a counter-opening to be made. The advice was executed and the patient soon afterwards died; more than six pints of blood were found extravasated in the thorax.

Another instance, that we cannot too highly apply the aid of these practitioners who understand the danger of the chest which still prevails in several parts of surgery. At the same time, be it said, that all who are interested in the improvement of the science should endeavor to ascertain the truth of any case about which we are offered. Hence, he deemed it proper to visit a case which was communicated to him by M. Saucerotte (the father), an excellent military surgeon, and which shows, that the erythema described by Valentin is, at least, not invariably attendant on extravasation of blood in the chest. A light housewife, who had received a thrust with a cane in the right side of the thorax, above the border of the pericardial sac, appeared to be going on very well for the first few days after the accident. On the fifth he complained of difficulty of breathing, weakness, and an inability of lying on the left side, without aggravating his complaints. He complained of a great sort of pain in the region of the liver, and at the top of the shoulder. His pulse was small and compressed, and rather hard than weak. The right side of the chest seemed larger than the left. On the eighth and ninth days the symptoms became more urgent, and the patient found no ease except in leaning on his right side, and supporting himself on a chair placed across his bed. The normalization of symptoms indicated an extravasation of blood in the right cavity of the thorax; but as the erythema which Valentin has described, was not apparent, such was entertained about the real nature of the case. When a counter-opening was made on the dead body, a pint of purplish blood flowed out.

When the symptoms first appeared, that an extravasation of blood in the thorax had really occurred, and the symptoms are very slight, the discharge of the confused fluid appears to provide benefit. However, before the operation is done, the greatest care of the pulse, the state of warmth in the extremities, and the cessation of great distress, ought to denote, that the hemorrhage is longer continues from the vessels; for, if this be not the case, a fresh quantity of blood soon comes extravasated again, and the patient die exhausted.

Another reason for methods of discharging blood from the thorax, viz. 1st, By placing the patient in a posture which favors the escape of the blood. 2dly, By introducing a syringe for the purpose of sucking it out, or a new channel, through which it is to flow; 3dly, By opening the wound, 4thly, By employing injectors; 5thly, By making an opening in a depending part of the thorax.

1. Blood cannot be removed from within placing the patient in a posture which is favorable to the escape of the extravasated blood, except when the wound is situated far in some part of the chest, and is large and direct in its course. Parr successfully adopted this method in the case of a soldier, who was wounded in three places with a sword, one of the wounds, which entered the chest, being situated under the right nipple. The man was first drawn by a surgeon, who understood anatomy. The patient was soon afterwards

attacked with considerable difficulty of breathing, fever, vomiting, spitting of blood, and white pain in the side. Pure, white was evacuated the next day, suspected that an extravasation had happened; immediately he cut out the sanguis, and placed the patient in a position in which his feet were much more raised than his head. Pure also accompanied him to hold his breath, and then introduced his finger into the wound, in order to make away some clots of blood which appeared as in others. By these steps the discharge of warm or cold masses of fibril, coagulated blood was effected.

3. The idea of drawing out of the thorax extravasated blood with a syringe, is rather ancient. The pipes of all syringes for this purpose should have bleed ends, but they injure the lungs. New tubes, constructed after the manner of the French syringe, have been frequently employed. Success relates a case, in which an incision of the latter sort was successfully employed. No syringe or any means with the mouth was requisite; it was found necessary merely to introduce the tube, and then withdraw the piston.

Lamotte used only a simple canula, which he introduced into the centre of the extravasation. Then having placed the patient as usual he proceeded to be the most favorable position, and requested him to hold his breath, he drew off the collection of fibril. His cases, numbered 120, 217, 218, show the success which attended this method. Although it might also have answered very well in case 214, Lamotte saw that the high situation of the wound would not have allowed all the blood to be discharged, and therefore he made a counter-opening. Thus the thorax was completely emptied, and a recovery ensued. When a canula is employed, authors recommend it to be introduced every day, till the last symptoms cease and no more fluid escapes through the cavity of the instrument. After having given vent to blood, it allows a bloody serum fluid to escape, and at a later period pus, which becomes a thicker and thicker substance the more the patient is in a recovery.

2. The cases in which a wound, complicated with an extravasation in the pleura, should be drained, are those in which the situation of the opening is favorable to the escape of the blood. The operation is performed with a curved stilet and a diatherme. The integuments and external muscles are to be divided in a perpendicular direction, and the intercostal muscles in a line parallel to the ribs. Care is also to be taken not to cut the vein the lower edge of the upper rib, and the intercostal artery be wounded. Details practiced was a soldier who was wounded at Bellet, in 1780, with a sword. Below the right nipple, whereby a direct opening was made into the pleura. When the extravasated fluid had been let out, blood ran into the patient into the wounded side during the night, and in proportion as the blood continued to be thus evacuated the breathing became free from oppression.

4. The methods above explained may be used when the blood retains its natural color of fluidity; but when it is coagulated, as often happens, they can be of no avail. In this circumstance, most authors direct a proper opening to be made, and tepid water then to be poured into the chest, with the view of loosening any clots, and the quantity and washing them out of the wound. The French writers, even the authors cited (Sabatier), most absolutely recommend the injection of various diluted, rubefacient decoctions, and of solutions of blood of mice, sheep, wolf, &c. What also these authors are witnesses of the great tendency to inflammation of the lungs and pleura, of which kind they can expect from such applications, is difficult to conceive. I am fully convinced, that the best means to be used in such cases, would be assisted of other such means.

5. When the wound is narrow, and situated at the upper part of the chest, the uppermost blood must be discharged, unless a counter-opening be made at the lower part of its cavity. The best place for making the opening, and the proper manner of executing the operation, are described under the head of *Pneumothorax*. As soon as the opening has been made, the blood flows out. Its discharge is then to be promoted by such a position as will render the opening depending.

The old surgeons, who had much more fear than the moderns of letting the opening heal, as a means employed to prevent the purpose of preventing the

exit, still at danger of another collection of blood or matter seemed to be used. However, as it does seem that an opening to be made in the pleura and lungs, beside the escape of which no fluid is contained in the chest, and which great arteries, veins, and every extrusion from the ribs, may be now reintegrated.

As large veins had the effect of hindering the escape of blood, matter from the cavity of the chest, some of the old French surgeons attempted a kind of work, but in the present state of surgery, I do not consider that it would be of all utility to make one a consequence of these contrivances. It may seem to cure respiration by keeping the opening from closing, their cause by a better thing for the purpose than a silver canula, with a view to keep it from slipping out the thorax, and two little rings or buttons, it is a contrivance with a shield. This shield may not close deeply enough to leave its inner orifice so nearly as very little further towards than the pleura cavity, so that it may not irritate the lungs.

When the patient has been drawn, he is to be laid in bed, with his head and chest somewhat elevated, and his limbs bent, in which position the breathing will be least oppressed. It is usual to recommend him to lie, as much as possible, on the side where the operation has been done. He is to keep himself as quiet a condition as he can. He is to get up very late, and, if his strength allows, he is to be tied from the arm, and this evacuation was to be repeated, with other sanguiferous means, when an urgency of the liver and inflammatory symptoms indicate, and the strength allows. Finding that to be too, he also constructing inflammation in the chest, which was principal source of danger, and in passing the force of the circulation in the thoracic vessels, and thus diminishing the tendency to blood coagulation.

The old practice of keeping wounds in the chest open is now nearly exploded, but if it was to be applicable, particular caution must be used not to cut veins and pleura of the dressings given into the cavity of the pleura. The case speaks of a French physician who had been under a crushing stress of matter of a wound in the thorax, and who coughed up, at months afterward, a large clot. A similar case is recorded by Richman. A man was stabbed in the side of the chest near the axilla, between his axilla and third rib. For a fortnight a great deal of blood was discharged both from the wound and the lungs. The wound healed; but the patient continued to be afflicted with considerable difficulty of breathing, an incessant cough, and to spit up a great deal of mucus. Three months afterward he coughed up one more which had slipped into the cavity of the pleura.

A violation of the antiphlogistic regimen must be made with very great circumspection. The antiphlogistic, making too frequently, and too soon, air compressions which may induce a pneumonia, hemorrhage and extravasation. Venousness is the chiefest of the others happen a foreign body in the wound, and eleven days after the operation for pneumonia. A soldier, who had been under in the chest with a wound above the right nipple, was attacked with fever, difficulty of breathing, weakness, and acute pain in the bottom of the chest. This syndrome induced Vesalius to order, that an operation had taken place; but he was afraid of making an opening in the chest, he fear the blood might still continue from the wounded vessels. However, in the patient remained in the same state the second day after the receipt of the wounds, and he could not breathe enough. Vesalius understood the operation, in which a considerable quantity of extravasated blood was discharged. The patient with pure blood at the instant. The receipt of blood continued for 48 hours, after which a favorable expectation took place in all the above wounds, and the case was cured and well. But the patient having repeated his wound and taken on with food, the symptoms of pneumonia ensued his death. Lamotte saw a person who had been under a crushing stress of matter of a wound in the thorax, and who coughed up a great deal of blood. He was under a crushing stress of matter of a wound in the thorax, and who coughed up a great deal of blood.

When the edges of a penetrating wound of the chest are to be brought together, writers say, that the first thing should be required to make a strong ligature

with the wound closed, and then a firm, strong expansion with it open, and so on, till as much of the air is discharged from the thorax as possible, and then the wound is to be accurately closed with wadding plaster. From what has been observed, however, in the article Emphysema, it will appear that when there is a slight opening into the thorax, that to admit the external air, the lungs are not so inflated, and remain so till the wound is healed and the air absorbed. When one of these wounds is treated, a collapsed state is induced, the best position in which it can possibly be for a certain time, and so, till the breach of continuity is repaired. Injuries by sucking the lung exposed by crushing the air from the cavity of the pleura may be attended in a paper, but, I apprehend, they will never be of real use in practice.

Purule sometimes continued a long while after wounds of the thorax. I never treated an instance in which there was a fistulous opening, out of which the so-called crab sufficient force to blow out a candle. The patient lived a long while in this state without suffering any particular inconvenience.

Another occasional consequence of a wound of the chest is a hernia of the lungs, the affection of which I believe met with its origin. A soldier, thirty years of age, was wounded with a bayonet in the right side of the chest, between the axillary part of the fifth and sixth ribs. The wound healed; but as the intercostal muscles had been divided to a great extent, and could not be approximated with precision, an empty space was left under the integuments, which allowed a piece of the lungs, as large as a walnut, to protrude between the ribs. The protruding enlarged in the time of inspiration, and grew smaller when expiration took place, occasioning every a night pain without any oppression in the chest.

Though no pains has been written on the subject of discharging blood from the chest in cases of extravasation within the cavity, the operation is very rare. During the last thirty years, I have never heard of its being done by any of the surgeons in London. In military surgery, however, the practice is occasionally resorted to—*Larrey, Mém. de Chir. Mil. t. 2, p. 125, 601*. No doubt, the true reason of the operation being uncommon is the obscurity in the diagnosis, the symptoms being all of an empirical nature. Even Larrey, generally so partial to operations, recommends the immediate closure of all wounds of the chest, excepting such as are complicated with injury of the intercostal artery, because (says he), unless very considerable vessels of the lungs are injured in which case nothing can be of any use, either no extravasation, or only a trivial one happens, which, under the employment of proper antiseptic treatment, may be dispersed by absorption.—(*l. c.* 127.) Regarding the general propriety of moving air wounds of the chest, I entirely concur with Larrey, Politien, Bayle, and Quercetanus.

Hunter, on a wound of a Chest of Newbury after an extraordinary accident, Jan. 1818. The injury here referred to is one of the most extraordinary on record; the shaft of the pig having been driven into the greatest distance between the sternum and lungs.* —*Mr. A. Halliday, in Edinb. Med. and Surg. Journ. vol. 11, p. 340; a rib having first a gunshot injury, in which a great part of the shoulder and scapula were, and the lungs and posterior cavity were exposed to the naked thorax of this case I saw four weeks since, having been at the field hospital, when the soldier arrived from the theatre, near Antwerp.*

Pressure of the Abdomen.—How one of the chief causes of danger is the tendency of the peritoneum to inflate. Every penetrating wound of the body is apt to excite this inflammation, which for some extends itself over all the viscera, and terminates in the death of the patient.

There are (says Mr. John Bell) a thousand instances in which the delivery of the peritoneum may be admitted. The wound of the small vessel and the side

of the chest, explain to us how quickly the peritoneum and all its contained vessels inflate from the most minute wound, although the cavity be altogether small to be visible on the outside and scarcely visible; for often, after dissection, no intestines are discovered ruptured, and no fluids have escaped into the abdomen. In subjects who die after lightning, we find the cavity of the peritoneum universally inflated. The operation of the Causticæ vesicæ is fatal, not from any loss of blood, for there is little bleeding; nor from the gases being exposed to the air, for patients also die at whom till wounds barely and where the air has no possible opportunity of infiltrating itself; but the cause proceeds still from the inflammation, which is always directed to extricate from wounds of the peritoneum, as well as of glands.—*Discoveries on the Nature and Cure of Wounds, p. 390, edit. 3.*

But although there can be no doubt that the wound, absolutely considered, is the most frequent occasion of this dreadful inflammation, yet it sometimes happens that the inflammatory consequences arise in relation to another kind of cause. If an artery be wounded, the contents may, under certain circumstances, be effused in the abdomen; if the liver, spleen, kidney, or any large vessel be injured, blood may be poured out, and grieve the viscera; if the bladder be wounded, bile may be effused; and if the bladder be pierced, the urine may escape into the abdomen. Now all these fluids are extremely noxious, with respect to the surface with which they affect, cause inflammation, and as such they give rise to inflammation of the peritoneum and viscera.

Wounds of the belly are divided, by almost all writers, into such as penetrate the cavity of the abdomen, and into others which only touch the skin and muscles.

The former differ very much in their nature, and degree of danger, according to they do or do not injure parts of importance contained in the peritoneum. The latter are not remarkably different from the peculiarity of other superficial wounds. The chief indications are to lower inflammation and to prevent collection of matter. A few particulars, however, is the treatment of superficial wounds of the abdomen merit attention.

Superficial Wounds.—The most serious lacerations, and their successors down to the present day, have been divided into wounds of tendons and ligaments, giving rise to very important consequences. Almost the whole front of the abdomen is covered with tendons, ligaments, and so on, and it is not unusual to see a profuse wound in this situation followed by extensive inflammation and the formation of abscess. At the same time, the patient is affected with a great deal of inflammatory fever. He suffers acute pain, sickness, vomiting, and considerable disturbance of the nervous system.—(*Callan, Spéc. Chirurg. Rouen, vol. 1, p. 102. Hoffman, l. c.*)

When the tension and swelling of the abdomen, shape, and shape sometimes occur, and indicate the collection of suppuration. The matter sometimes accumulates in the ilio-colic sheath of the cæcum, and when the collection in this situation remains undischarged until a pointing appears, no more does the suppuration, or it is rejected, than an extraordinary quantity of matter is discharged. The surgeon should carefully examine the nature of this kind of case, at first, is frequently not sufficient alteration in the appearance of the integuments to denote either the existence or the extent of the suppuration.

Such an abscess forms an remarkable exception to the etiological causal rule of showing some phlegmonous processes to form of their own accord. In the present instance, there is an spontaneous expansion (involving between the abscess and the skin, and repelling into the natural progress of the matter to the surface of the body as previously as the transposition of a phlegmonous focus. But even in this instance the propensity of pus to make its way outwards is called out to form extensive influence. Though there is only a thin membrane (viz. the peritoneum) between matter collected and the cavity of the abdomen, the abscess, after a time, mostly points externally.

The proper treatment of this case is to prevent the suppurative accumulation of matter, and rapid increase of mischief, by making a depending opening, and

times at the very lowest part of the shaft of the resin
44406, 100 lbs., as soon as the judgment of matter is
fully confirmed.

However, there is a time in which it is advantageous and justifiable to make an early diagnosis of a presumed animal, in order to prevent the photo-diagnosis at macroorganisms, it is unquestionably the present moment. In fact, indeed, is particularly recommended by Collins, in relation to the strictest anthropogenic control.—*Don Spat. Civ. Mediterra*, vol. 3, p. 62, 1971.

Sometimes the scar is found between the eye and the internal oblique vessels, and spreads to a great extent. The part may even assume such a size as the abdomen, and the cancer follow. Such an example is recorded by Dr. Cresson, of Wakefield. In this instance, however, the disease preceded the carcinoma, ran a wound.—*See Edinb. Med. and Surg. Journ.* vol. 8, p. 123.

[illegible]

Wounds of the abdominal muscles are sometimes the most difficult to suture, and the patient kept quiet in bed. A very important point in the treatment of wounds of the parietal part of the abdomen, is to afford a degree of support to the wounded parts, so that the pressure of the viscera may be avoided. The sides of the abdomen are almost wholly composed of solid parts, which easily yield. No part of the thorax or ribs of the abdomen is supported by a bony structure, and the viscera are, for the most part, covered less completely, and are, consequently compressed by the abdominal muscles and diaphragm. They are liable to protrude whenever the resistance of the surrounding parts is not sufficiently powerful. Hence, all wounds of the abdomen, especially those in which biliary impaction and necrosis have been met, demand exact attention to the means of supporting the wounded parts, and that, though the patient may think it should not happen to be avoided. The patient ought to keep as much as possible in a horizontal position, and suitable compresses and bandages should be applied. And, in order to guard against hernia, a patch should be supported in this way a considerable time after the wound is healed.

The performance being discussed by means of fuel air substance with the same volume of the alcohol, requires there is always some risk of the inflammation of these parts extending to that membrane. The danger must be avoided by the extreme employment of a hygienic treatment. What renders the reaction more dangerous is, that where one part of the period is affected, the neighbouring usually spreads with particular rapidity over the whole extent, and so it often falls.

As important rewards of the program are to be based on the general principles applicable to all teaching awards in other institutions, it is hardly necessary to state that these by the first intention, if possible, are not to be attended.

—The first thing which the suspect is generally made to know, when he is brought to a show-up of the fact is, whether the accused possesses the curfew of the accused, and whether any of the various are injured.

[illegible]

When the vessel is sufficiently large to admit of

Singer, a surgeon, can always check whether the baby actually falls into the abdomen, because not much time elapses between the time the baby is cut open and the time that cavity, and the contained contents, may be taken out. There is no chance of deep probes, however, and so from the possibility of mistaking the inside of the stomach for the rectum muscle for the uterus, if the probe is used, and since the veterinarian is not a medical graduate, particular caution should be used in forming a judgment of the nature of the mass, but the presence of such anal sphincter, that a very short tube will make the insertion of probe considerably better to use. Any investigation of this kind should always be considered, if possible, when the patient is exactly in the same position as when he lay in the time of parturition, or when he was born. Especially, if the animal were somewhat to be kept in the state of the position of the cavity or its thickness. This short experiment is not very easily completed. It is well known to the contrary, and the space, around the cavity of the abdomen, is not completely filled with the various organs, and in a general, we suggest, fluid would not be likely to fall into the bag of the peritoneum, as an ordinary person might suppose. And if it were poured out, it would be quite as likely to fall into the cavity of the abdomen as to fall into the cellular substance of the stomach. The least curiosity of the animal, or a pair of lower, or overactive, laying against the abdominal side of the body, would also completely prevent the London from passing into the abdomen.

When a considerable quantity of blood issues from a wound of the skull, we, without previous examination, are certainly, that some large vessel has been torn or injured. Excepting the epigastric artery, which crosses the forepart of the abdomen, along the right margin of the rectus abdominis, no large vessel is distributed so near the surface and large vessels. At the same time, the serving of particular notice, that a large artery might be exposed in the shoulder, and not a drop of blood be discoloured from the wound.

In such cases, the consequences require a healthy and to a suspicion of what has happened. The most common complaints of various diseases are: loss of appetite, loss of weight, and if the illness should not specifically come, these symptoms are also called disorders.

Examples like the catarrhs of the second law, activity of the abdomen is from the first law, namely, being indicated by the evase of this, have some feces, in other words. The vomiting of a considerable quantity of blood, or its discharge by stool, and also the other signs, are from the first law, namely, they are from a wound which does not usually penetrate the abdomen, or the kidneys, and, and thereby may be held to be one of the abdomen, because they are not outside of the cavity of the abdomen.

When some of the above symptoms occur, while neither this danger, nor the grave risk to be apprehended, when some of the fluids become to be absorbed in the various receptors in the abdomen, transferred from the viscera, when the pulse becomes small, and the pain is not excessive, there is reason to hope that the vascular has not injured parts of greater importance than the integument and muscles. (Etiologia, 20.)

[illegible]

The edges of a printed page using the system, is watermarked with layers of the system, and is to be used together with sticking glass, in the case of the same.

at once lay the belly flat and close the wound. By placing the walls of the abdomen are not flaccid, nor the cavity empty, but the abdomen full, and that the muscles which cover it contract strongly, the effect being to exert a particular, for the moment that the belly is contracted, the action of the vessels would have all part of the blood; the contraction of this action is necessary to regenerate the wounded surface; and the contraction of the abdominal muscles and the diaphragm against all the vessels of the abdomen, prevents any access of air externally, thus though we should hold such a wound open with our fingers, no air could pass into the abdomen, further than so that place is put into it first treated with the finger, whose we thrust it into the abdomen. Nothing is necessarily exposed to incise, except that piece of intestine which is without the abdomen, or that which we see when we expose a small piece of the bowels by holding aside the lips of the wound. The pressing forward of that piece, and the protrusion of a portion of the gut, prevents always in the case of the wound, the pressure from behind, keeping that piece protruded, so that it is with difficulty we can push it back with our finger; this increased pressure in all directions is an absolute security against the access of air. The intestine comes out, not like water out of a bottle, the sides of which tube are supplied by air existing into the bottle, in proportion as the water comes out; but the gut is pushed down by the action of the muscles made of the abdomen, and this action follows the intestine, and keeps it down, and prevents all access of the air, while the gut contracts thus protruding, so whether it be reduced; for if it be reduced, the walls of the abdomen yield, allowing it to be thrust back, but admitting no air. Those who want to know the effect of air, distilled within the cavity of the abdomen, must make other experiments than merely cutting open the belly;—they must give us a fair case, instead of this unnecessary word. We will not allow them to say, when they cut open the belly of any creature with a long incision, that the inflammation comes from the air; much less shall we let them say, when they open the belly with a smaller incision, not by that little incision the air goes into the abdomen, and that all the bowels are exposed to the air. (Lectures on the Nature of Wounds, p. 323, 324.)

In answering to the question, whether air is so important to the cavity of the body as many have supposed, Mr. John Bell continues with much spirit and success the opinions published on this subject, by Dr. A. Moreau, in his account of the horse section, as the attached quotation will show. "That the virtue should believe the first superficial impression that strikes them of air entering a wound were, in my no mean surprising; but it is so certain that men and in philosophy should adhere so strongly an opinion as that without some kind of proof. Thus the air which we breathe, and which we feel upon the surface so hard and disagreeable, would have to express a virtue in the normal parts, which would there be a stimulus more violent and more dangerous than the air, is not to be believed upon slight grounds. I do often hear Mr. John Bell that it is useless to be proved that this fluid, which seems so bland and pleasant to all our senses, and to the outward surface, is yet a horrible stimulus, when admitted, as a celebrated author grandly expresses it, 'that the deep recesses of our body.' (Moreau's *Revue Médicale*.)

With how much reason Mr. John Bell objects, that this doctrine is unscientific, will be manifest to every man of our discernment and impartiality.

The air, for instance, escapes from the lungs, in a freshened life, and that goes about into the blood, then into the capillary vessels; then the capillary vessels contract, and the air is absorbed; but often without any contractions, with very little care and assistance on our part, the air is absorbed, the fullest capillary, and without inflammation of the chest, or any serious danger, the men get well. How then is the air, within the cavity of a dead air filling the thorax, and opposing the lungs, without any dangerous inflammation arising?

That the air may be pushed into the capillary vessels covers all the body, without causing inflammation, in every part from the more dependent cases of emphysema, where the pressure, after living cells at sea

dry, have died, set from inflammation, and from expansion slowly, the body being so crisscrossed with vessels, even the vessels have, upon dissection, that fixed in tension to open bloodless. We have also many instances cases of this kind, which prove this is not perfect contraction. Soldiers and sailors sometimes break the vacuum with a lance, introduce a blow gun, and blow it up in an emergency, without being hurt, by which they hope to escape from the vacuum. The old story of a man who was so wicked as to make a hole in his child's head, and blow it up, that he might show the child in the streets of Paris for a wonder, is well authenticated; and I have, I think, met a soldier, who knew how to do this, would blow a top every evening, and squeeze it out when he put the child to bed at night. Some violent hunters having a prize at a soldier, found him lying dead under a hedge; they made a little hole in his neck, and then his spirit he was like a bladder, as the English proverb the disease of emphysema, his a wretched man." (P. 324, 325.)

After many other pertinent observations, blended with appropriate satire on the extravagant notions advanced by Moreau, on the bad effects of the air, in this case, operations for testis and hydrocele, the English section, Dr. John Bell now jumps into the air, to indicate the propriety of Dr. Moreau's proposition that the gut appears with the force of a steam bath is so to inflate the air. "This, though it may seem to be a strong piece of wit, was really proved in some recent experiment. But since Mr. John Bell the admission of atmospheric air, as a stimulus, while compared with the great increase of inflammation, of testis, of hydrocele, of the disease, nature of the lungs, is no more than the drop of the bucket in the waters of the ocean. And it is just as just as to say, that after such droughty operations, some organs are inflated by the admission of air, as it would be to say (as Moreau do), that when a man is run through the peritoneum with a red hot poker, that the heat and prickliness are inflated by the admission of the air." (P. 327, 328, 329.)

Enough, I conceive, has been said to dispel all the idle fear and prejudice which have prevailed concerning the bad effects of the air in wounds of the abdomen, as well as several other cases. When I lastly present a case as Dr. Alexander Moreau, which was disturbed by such apprehensions, it is not without this many a poor ordinary member of the profession should have been terrified nearly out of his wits upon the subject; and for quailing this alarm and exposing its absurdity, I freely thank Mr. John Bell for saying of scientific praise.

It cannot, in all cases of wounds of the abdomen, be an excellent rule never to be efficient about wounds which may take place, nor to take pains by such experiments to have been devised for setting positively what best is wounded. It is quite too much to interfere when the signs of the present condition are suspicious which may be wounded. A great deal of harm is frequently done by bleeding and discharging the wounded parts more than is necessary, and it is not known, that wounds of the abdomen with alarming symptoms frequently have a favorable termination. Swords, lances, and other weapons sometimes pass completely through the belly without the least suffering afterward any threatening symptoms, or indeed any effects which, obviously considered, would authorize the inference that the victim had been at all injured. Severe inflammation may be set on in suppuration, and when set is formed it is soon, often absorbed again. Nothing then is to be done for the discharge of pus, but rather to the abdomen, unless the fluctuation and extension of the abscess be very distinct, and the quantity and position of the matter clearly profuse. If inflammation under these circumstances, the surgeon should make a cautious puncture with a lance.

Prevention of the Future.—The condition of small intestines are the most liable to protrusion, but in large wounds the great intestines are wounded, and upon the liver and spleen may project through the opening. The general expression indicating a protrusion of the parts are sufficiently obvious; but it is desirable attention, that in the subjects the above membranes may project from the wound, and yet be universal of the appearance of success. The ap-

and symptoms are to be collected from a knowledge of the natural situation of the parts, and indicating what region of the abdomen is wounded.—(Cullenn, *Epileptic. Therap.*, t. i, 792 and 793, edit. 758.)

From penetrating wounds considerable portions of the bowels are sometimes protruded; and though these viscera may not have received injury, yet their being displaced is immediately productive of fatal consequences.

The best mode of governing such mischief, is to return the viscera into the cavity of the abdomen as speedily as possible. Almost all authors recommend returning the displaced parts, previously to the attempt at reduction; but, in giving this advice, they seem to forget, that while time is lost in this poperly necessary measure, the protruded bowels suffer much more harm from exposure, than is to say, from the very circumstance of their being out of their natural situation, than they can possibly receive good from any application made to them. No kind of emollient can be said to be useful as the internal warmth and moisture of the cavity of the abdomen. In order to facilitate the return of a protruded piece of intestine in situation, the abdominal muscles should be relaxed by placing the patient in a supine posture, and the large intestine emptied with a clyster. As spontaneous haemorrhage, if it is not checked, that hemorrhage should delay the attempt to reduce the part until the vessel has stopped. So, this measure is only counteracted as soon that may become serviceable in case the viscera cannot immediately accomplish the object in view.—This necessary caution always to be observed before the intestine, the intestine before the protrusion; but the last protruded portion of each of these parts ought to be the first reduced.

It is only when the intestine and omentum are free from spasms and mortification, that they can be safely to be returned into the cavity of the body without hesitation. Also, when the protruded parts are covered with sand, dirt, or other extraneous matter, they should be tenderly washed with a little tepid water.

For the reduction of the parts, the fore-fingers are the most convenient, and it is a rule to keep the position that returned from protruding again by one finger, until it has been followed by another position introduced by the other finger. The second part is to be kept up in the same way by the finger next to return it, and so on, till the displaced parts have all been put into their natural situation.

In attempting to reduce a piece of protruded intestine, the patient should be placed in the most favorable posture, the head and chest should be elevated, and the pelvis raised with pillows. Nothing can be more absurd than the advice to put the thorax rather lower than the pelvis, in order that the weight of the viscera may tend to draw upwards the protruded parts. This is another erroneous idea, arising from the ridiculous supposition, that a great part of the abdomen is actually an empty cavity. The relaxation of the abdominal muscles is a much more rational and useful object. When this is properly attended to, the above directions are observed, and the wound is not extensively lacerated, in relation to the bulk of the protruded viscera, the parts may generally be reduced. But in addition to what has been already stated, it is necessary to remark, that the pressure should be made in a straight direction into the abdomen; for when, much obliquely towards the edges of the wound, the parts are drawn in, to suffer contusion, without being reduced, and even to pile between the layers of the abdominal muscles, and become strangulated. When the wound is in the front of the abdomen, pressure made in this unskillful way may force the viscera into the sheath of the rectum muscle, and cause the same serious symptoms as arise from an incisional hernia.—(See *Hernia*.)

When the reduction seems complete, the viscera should more loosely be held, by introducing the finger into the cavity of the abdomen, so as to feel that the parts are all snugly reduced, and suffer no constriction between the edges of the wound and the viscera in the abdomen.

A difficulty of reduction may arise from the protruded intestines being dominated with feces or air. In this circumstance, the contents of the gut may frequently be made to pass by degrees into that portion

of the intestinal canal which is within the abdomen. In order to accomplish this purpose, the surgeon must press the contents of the bowel towards the wound, and if he succeeds in emptying the gut, he will consequently experience equal success in his next attempt to reduce it in the abdomen.

Sometimes, in cases of narrow straits, considerable pieces of intestine protrude, and cannot be reduced without doing immediate violence to the bowel. Under these circumstances, the dilution of the bowels is indispensable. However, when the reduction seems at least a matter of impossibility, an attempt to the reduction of the rectum, if the surgeon be careful to relax the abdominal muscles, draw a little more intestine out of the wound, and gently press the contents of the bowel through the constriction in the abdomen, he will frequently succeed in reducing the parts without using the knife.

When such expedients are unavailable, the dilution should be made in a direction remote without endangering the sigmoid artery, and, if possible, in the same line as the muscular fibres.

We are also advised to make the intestine spread rather than downwards, where it can be done with equal convenience, because it is supposed the first direction will be followed by less danger of necrosis.—(See *Hernia*, *Medical Operations*, t. i, p. 229, et seq. Cullenn, *Epileptic. Therap.*, t. i, p. 793.) If, however, the appearance of the wound corresponds to the direction of the superior ligament of the liver, within advice making the dilution at the lower angle, in order to issue no risk of hemorrhage from the vascular system. In the adult this vessel is generally obliterated, and lined with a ligamentous substance; though it would appear that, in a few instances, it remains pervious to the bowel. Hitherto no young persons have died in consequence of a stick in the belly between the false ribs and the umbilicus, and on opening the body, the intestines issued from a wound of the middle of the abdomen. It has been feared also, that cutting the superior ligament of the liver might give rise to such a displacement of that vessel as would interrupt the freedom of respiration, or obstruct the circulation of the blood in the venous system. But the supposition is unfounded; for Richter found this ligament ruptured and separated towards the liver in a violent Abdominal bleed down whose respiration had not suffered, any particular disturbance during her illness.—(See *Medical Operations*, t. i, p. 229, 231, et seq.)

The incision should never be deeper than absolutely requisite, as laceration is much disposed to occur wherever the peritoneum has been divided. The operation may be done with a curved bistoury and a director, much in the same way as is done in cases of strangulated inguina.—(See *Hernia*.)

After the death of Wateline many cases presented themselves in which the bowels and omentum protruded, and in several of these examples the reduction could not be effected before the viscera had been enlarged. So lightly also were the parts put, that the operation was sometimes for free being easy.

Instead of enlarging wounds of the abdomen, a ligature proposed to cut the air from the protruded intestines, by making small punctures with a needle, so as to loosen their adhesion sufficiently to make them reducible. The suggestion first originated with Pott, who declares, that he had practised the method with success. However, his contemporary, also informs us, that his plan was adopted by another surgeon, in an instance where the epigastric region was distended, and a large portion of the intestines protruded in a strangulated state. Peter Lever, an English surgeon, likewise assures us, that he frequently adopted the practice when other means failed. Garside, Sharp, and Van Meulen are all advocates for Pott's proposal; but they recommend the employment of a round needle, which will surely separate the fibres of the intestinal vessel without cutting them, as a far more rational, simple, and useful mode would undoubtedly do. These gentlemen, however, only mention the practice when the quantity of protruded intestine is great, and the bowel is so remarkably distended with air, that it would be impossible to reduce the part, though the wound were enlarged, and every thing else put in practice likely to bring about the reduction. But, as Sabatier remarks, the punctures must be carefully made, it made with a fine needle, since they will be in-

medicinally stopped up with various substances, with which the wound is constantly covered, and if the surgeons are made with a broad triangular section of a very large round case, as Deane and Croquet advise, they will be highly dangerous, inasmuch as they are likely to give rise to inflammation, and even to extrusion of the abdominal contents.—*Wanderer's Operative*, t. i. p. 16.

That small punctures in the breast would not prevent the progress, but be obstructed by the violence of the wound, is a fact which has been for a long time well known to surgeons. Chalmers, among others, has particularly noticed it: "any puncture made full size with any sharp instrument, whether lancet or other, is immediately closed." &c.—*Syst. Clin. Med.* t. 3, p. 704.

It was the consequence of small punctures being made, that led Deane and Croquet to recommend the use of a large round needle. "vous que l'ouverture est plus grande par les instruments dont les autres sont munis." But they were also aware of the danger of exposing such an instrument, since they give as directions how to proceed, in order to prevent inflammation and infiltration: "On percevra l'épave sans des videries chirurgicales en point, avant de réduire l'ouverture, sans avoir de fil dans la partie se maintenir qui repousse le piquet pour la fixer contre les bords de la plaie extérieure; et l'on cautérise par les règles générales l'épave qui est piquet pour éviter."—*Traité des Maladies Chirurg.* t. 3, p. 123. Richardson is still an advocate for puncturing the breast, for which operation he fully recommends a small hydrogale needle.—*Wanderer's Clin.* t. 3, p. 326, et 4.

Mr. Treves, one of the latest and best writers upon this subject, most properly joins in the condemnation of the plan of puncturing as protruding wounds. "But, said and others protested against this practice, on the very sufficient ground of its necessity. In Paris very truly says, it is useless as well as dangerous practice; for the opening made by a round needle causes pressure to the contained air." Mr. Treves then cites two cases, showing that a very small hole in a breast will not prevent its becoming distended with air.

"A man was brought to St. Thomas's Hospital on Saturday, the 30th of June last (1811), who had been stabbed in the region of the epigastrium, on the left side of the abdomen, by a saw-bite. He died in eighteen hours, apparently from the sudden rupture of hemorrhage which had taken place within the belly. About half a pint of blood was protruded. The gut was highly distended, and so much distended, notwithstanding it was punctured in three places, that the protrusion of the intestines required it to be freely released before it could be returned. The aperture, given in fact, adhered by the nature of the fluid."

"It happened upon the case of Captain Richardson (Ann. Reg. June, 1800, for the murder of his father), that the intestine had been exposed protruding through a wound near the left nipple, and had been exposed the first or the last; that the gut had passed through one hole of intestine, and protruded again; that the wound of intestine was only as a hole; that the collection could not be accomplished upon the general wound was closed; and that the intestine was then returned, and the integuments sewed up."—*Treves's Reports of the Dissections*, p. 174, 175.

With respect to this last case, however, I must observe, that it does not satisfactorily prove what the author intends, namely, that the breast was distended with air though there was a wound in it half an inch long; for the evidence does not inform us that the difficulty of reduction was owing to this cause. I have seen a very small portion of intestine protrude through a wound, and baffled all endeavours to reduce it for nearly an hour. The first case noticed by Mr. Treves, however, is more explicit and interesting, and we are to infer from it, and the observations of Mr. Chalmers, that the puncture made is an incision, not closed by nature, as Deane and Croquet have asserted, but by the adhesion of blood.

As the above evidence has been recommended by writers of some weight, I thought that the subject should not be passed over in silence, and in doing so, I am, as the reader perceives, not only confined to the method. The plan does not furnish the evidence

of the operator; there is not even a satisfactory answer in favour of the practice; and though it may be said, as Deane and Croquet have said, that the puncture is made by a large needle, which would give the least knowledge of the extent of the wound, yet every surgeon who has seen the smallest puncture made in the breast, must be satisfied with great degree that it would not be closed by a wound of that size and nature. Besides, the air may frequently be proved to be of the incision in a short way, as I have already described.

A wound of the abdomen, attended with one of the most considerable protrusions of the viscera, has been ever read of, as recorded by Mr. Hays, surgeon at Kingston.—"August 20th, 1808 (says this gentleman), I went to North Mills, where, four miles west hence, I saw John Brown, at 72 years of age, who had sustained a wound in the abdomen from a part of a wheelbarrow. On my arrival, which was little more than an hour after the accident, I found the patient in a very alarming situation; the great side of the stomach, and the whole of the intestinal canal, distended and extruded, protruded within the abdomen, having protruded through the wound. The protrusion was about half of the body, commencing at about two inches below the umbilical circle, and extending to a straight line some five inches in length, distant from the centre of the rectum, and it was quite round, and had seemed so as to empty the stomach. Very little blood was lost. I immediately proceeded very carefully to examine the protruded viscera, each of which were wounded, and reduced them as quickly as possible beginning with the stomach, and following the regular course of the intestine; at the latter portion of which I finally discovered the cause of the protrusion. It was a piece of some pain during the reduction, though not much, and expressed great relief when the parts were completely returned. I now desired an assistant to lay the patient on his back over the wound, and make some pressure upon it; for I found that if the parts would not have protruded again by the action of respiration, which was oppressed and laborious. I thought the state of the wound together with the nature, requiring first above pressure, and passed the needle on each side, quite through the intestines with the perforators, &c. The wound was now dressed with adhesive strapping, and covered with a bandage."—(Vide *Edinburgh Medical and Surgical Journal*, vol. 3, p. 125, &c.)

This case is interesting, for attending to the treatment of protrusions of the viscera, and the nature of the parts being left exposed for some time, then, on a later, a recovery ensued, under the judicious employment of bleeding, incision, &c.

In La Charité de St. Etienne, or Lyons, after the battle of Waterloo, the number of protrusions of the viscera which fell under my notice was much more considerable than what I previously had any idea of ever meeting with. I well remember, in my own part of the hospital, two protrusions of a large portion of the stomach, three of the smaller, and six or seven of the mesentery, mesocolon, &c.

Whether a surgeon should be and when despatched intestine is a subject which will be treated in considering wounds of the abdomen.

Some of the exposed intestine may have mortified before the arrival of surgical assistance. In such a case, this event is rare; but in some of the most severe, it is not uncommon. The prognosis is explained in the article *Wound*.

When the protruded intestine is in a state of inflammation, or in a state of relaxation, or in a state of spasm, the surgeon must first be set every day right. When the inflammation is considerable, the bloody reaction of the dilated part, and the requirement of suppuration, means, will often prevent progress. The daily, however, darkened colour of the intestine may induce the practitioner to suppose that the part is already mortified, or near being so, because, and consequently, to set every day, setting a day in several situations. But before reaching the conclusion of the case, the surgeon, in France, will state that it is not in a state of necrosis. The complete recovery of a portion of intestine in a short time is always a matter of uncertainty; but the prognosis of speedy recovery of the part is the most

will pour out their force into the abdomen and prove fatal; though we should settle that our fair and good dissection in the theory, we find that it will never answer in practice. Soldiers never die from the most desperate wounds; and the most likely reason that we can assign for it is the nature of the abdomen; the surface, equable; and gentle pressure; and the active disposition of the peritoneum, ready to effuse with the slightest touch. The wounded intestine is, by the natural pressure, kept close to the external wound, and the peritoneum and the intestine are equally inclined to adhere. In a few hours that adhesion is perfect, which is to save the patient's life, and the life of the wounded intestine is given to the lips of the external wound. Thus is the side of the abdomen distended to the inner surface of the abdomen; and, though the gut comes out in front while the wound is open; though it often falls down out more freely while the first inflammation lasts; yet the force resists this regular course whenever the wound is disposed to close.—(John Bell's *Discourses on Wounds*, p. 322, 323, 324.)

The foregoing extract, though short, is a careful study, contains such observations as are well estimated to make the reader understand, that the abdomen is in reality not a cavity, but a compact mass of coexisting and contained parts; that the close manner in which the various surfaces are constantly in contact must powerfully oppose extravasation; and that, in fact, it often entirely prevents them. The passage of impressions up to the cavity of that space propensity to the adhesive inflammation which permeates throughout every peritoneal surface, and which not only often has the effect of successively limiting effusions of the contents of the viscera, by uniting the parts together, but which, even when an extravasation has happened, beautifully confines the effusion close in its mass, and separates it with each adhesion of the parts in such other as are rapid in their solution and efficient for the purposes of limiting the extent of the effusion, and preventing the initiation of the extravasated matter from affecting the rest of the abdomen.

It is to Bell that I am indebted for more correct notions of thinking upon the foregoing subject; and it is with great pleasure that I have referred to his valuable observations.—(See *Mem. de l'Acad. de Chir.*)

But notwithstanding the reciprocal pressure of the coexisting and contained parts against each other, and the useful effect of the quickly arising adhesive inflammation, in all penetrating wounds of the belly, complicated with laceration of the viscera, we are not to suppose, that extravasation never happens; but only that it is much less frequent, than has been commonly supposed. Mr. Treves, with much lucid industry, has succeeded to trace, more minutely than any preceding writer, the peculiar circumstances under which effusions in the abdomen are likely or unlikely to happen. "It being admitted (says he) that there are cases in which effusion does take place, it is easy to conceive circumstances which must considerably increase this event. If, for example, the stomach and bowels be in a state of tension, the matter which follows the injury will exclaim that side. If the extent of the wound be considerable, the matter will more readily pass through the wound than along the canal. A wound of the same dimensions in the small and large intestines will most readily exclaim, the former than the latter, because it bears a larger proportion to the cavity. Incised and punctured wounds admit of the adhesion of the cut edges or the eversion of the internal end of the gut, so as to be in many instances actually obliterated, whereas, lacerated or elevated openings do not admit of these salutary processes. Again, in a transverse section of the bowel, contraction of the circular fibre closes the wound, whereas, in a longitudinal section, the contraction of this fibre enlarges it. Such (says Mr. Treves) are the circumstances which concur, in a greater or less degree, to facilitate the tendency to effusion."—(On *Exterior of Injuries*, &c. p. 13, 14.)

After the details of some experiments and cases, the preceding author enters, among other mechanisms, the following:

1. That effusion is not an ordinary consequence of penetrating wounds.

2. That if the gut be full and the wound extensive, the surrounding pressure is overcome by the internal

action of the bowel tending to the expulsion of its contents.

3. That if food has not recently been taken, and the wound amounts to a division of the gut, or, nearly so, the exertion and contraction of the fibres of the gut prevent effusion.

4. That if the canal be empty at the time of the wound, no subsequent state of the bowel will cause effusion, because the supervening inflammation agglutinates the surrounding surfaces and forms a thrombus; but the effusion takes place from a hole at the wound full, provided it remains a certain period of its cylinder tense, the wound not admitting fully in a semi-division of the tube, for then the tension and contraction are too partial to prevent an extravasation.

5. That when, however, air has escaped from its bowels, or blood has been expressed in quantity within the abdomen at the time of the injury, the distance made to effusion will be less effective, although the peritoneal pressure is the same, as such fluids will yield more readily than the solids naturally in contact.—(P. 15, 16, 17.)

6. That though extravasation, as just shown, is preventing wounds, it follows more generally in cases where the bowel is ruptured by blows or fallings on the belly, while the integuments continue unscathed.—(P. 18.)

7. That when the bowels are irritated by absorption, there is more tendency to effusion than in cases of wounds.—(P. 18, 19.)

Mr. Treves proceeds to explain the reason of the greater tendency to effusion in cases of laceration than by violence thus in cases of abrasion, "by the difference in the nature of the injury which the wound wounds were provoked by a sword or burn, it is in one case, in kind or affecting, in the other. A wound by a sword or burn could only take place under a decided state of the bowel, a roadster and falling in effusion, and from the nature of the part, a rupture so produced would seldom be of decided extent. The process of absorption, by which an aperture is formed, commences in the internal coat of the bowel, which has often discovered a more extensive lesion than the peritoneal covering. The peritoneum can scarcely be torn, as it is a point or line; the internal wound is an actual loss of substance. The consequence of this difference is, that while the former, if small, is glued up by the effusion from the cut vessels, or, if large, is nearly obliterated by the full eversion of the viscous coat, the latter is a permanent rent."—(P. 19.)

How much Mr. Treves and Mr. John Bell differ in opinion upon these latter points, will appear from the following passage: after admitting to the admission, which makes place between the wound and the peritoneum, under a variety of circumstances attending disease, Mr. John Bell observes, "This is a subject which the chief difference, in point of danger, lies in the lacerated and a wounded intestine; for, in a wound, there is, as we should suppose, no time for adhesion, nothing to keep the parts in contact, because to stop the effusion might be produced. This is as clear as day in a slow disease, tedious inflammation, whereas first, and phlegm and burning afterwards, sometimes a focus remains discharging pyrexia, and sometimes there is a perfect cure. If a wall shell, a large one, a small, or any dangerous form be introduced, it stops in the stomach, causing swelling and dreadful pain; it first lacerates, then it tears, and then it ruptures; the bowels open, the food is discharged at every breath, till the fluids gradually become and leave it full; then the stomach is torn with a violent rent of a vessel, the blood from the wounded artery vessels, or the food itself, so often pours out in great abundance, and the patient dies."—(On *Exterior of Injuries*, &c. p. 13, 14, 15.)

The author afterwards proceeds to explain how, in cases of penetrating wounds, the complete state of the containing and contained parts, and the constant and variable pressure which the viscera exert, frequently hinder effusion.

Which of these positions is most correct I cannot determine to determine; and whether Mr. Treves' cases are deviations from what is most common, or only be decided by a comparative consideration of a greater number of facts. When the viscera are lacerated, and thus rid themselves of foreign bodies, the great force of the same is forced indubitably affects it

will pour out their force into the abdomen and poorer still; though we should wish this as a fair and good discussion in the theory, we find that it will never answer in practice. Soldiers moreover daily find the most desperate wounds and the most fatal wounds that we can imagine for us the effects of the abdomen; the external, equine, and groin wounds; and the active disposition of the peritoneum, ready to inflame with the slightest touch. The wounded intestine is, by the internal pressure, kept close to the external wound, and the peritoneum and the intestine are equally inclined to adhere. In a few hours that adhesion is begun, which is to save the patient's life, and the life of the wounded intestine is given to the life of the external wound. Thus in the side of the intestine is the inner surface of the abdomen; and, though the gut runs out in front while the wound is open; though it often runs from out more freely while the gut is inflamed, but, yet the force retains their regular course, whether the wound is closed or open."—*John Bell's Dissections on Wounds*, p. 326-327, ed. 3.

The foregoing extract, though directed to a careless eye, contains much observation as are well explained to enable the reader to understand, that the abdomen is in reality not a cavity, but a compact mass of contracting and contained parts; that the close manner in which the various surfaces are constantly in contact must powerfully oppose extravasation; and that, in fact, it often actually prevents them. The power of the adhesions in with the ability of that quick propriety in the adhesive inflammation which prevails throughout every peritoneal surface, and which not only often has the effect of permanently binding off the ends of the vessels, by uniting the parts together, but which, even when an extravasation has happened, immediately coagulates the effused blood in one mass, and surrounds it with such adhesion of the parts as each other as not move in their location and efficient for the purpose of limiting the extent of the effusion, and preventing the intrusion of the extravasated matter from affecting the rest of the abdomen.

It is to be noted that surgeons are enabled to make correct decisions of plucking upon the foregoing subject; and it is with great pleasure that I here refer to the valuable observations.—*See Wm. de F. Jones, de Chir.*

But notwithstanding the natural pressure of the contracting and contained parts against each other, and the useful effect of the quickly acting adhesive inflammation, in its penetrating wounds of the belly, complicated with laceration of the viscera, we are not to suppose, that extravasation never happens; but only that it is much less frequent than has been commonly supposed. Mr. Trauer, with much laudable industry, has endeavored to trace, particularly those are preceding writers, the particular circumstances under which effusion in the abdomen are likely to take place. "It being admitted (says he) that there are cases in which effusion does take place, it is easy to conceive circumstances which must considerably facilitate this event. In the example the stomach and bowels be in a state of engorgement, the vessels which deliver the injury will maintain that state. If the extent of the wound be considerable, the matter will, more readily pass through the wound, than along the canal. A wound of the side discloses in the small and large intestine, but more readily extrudes the former than the latter, because it bears a larger proportion to the latter. Internal and peritoneal wounds admit of the adhesion of the cut edges or the eversion of the internal coat of the gut, so as to be in many instances actually obliterated; whereas, lacerated or incised openings do not admit of these salutary processes. Again, in a transverse section of the bowel, compulsion of the circular fibres closes the wound, whereas, in a longitudinal section, the contraction of the fibres enlarges it. Such says Mr. Trauer are the circumstances which combined, is greater or less degree, facilitate or disallow the tendency to effusion."—*On the Effects of Lacerations*, &c. p. 13, 14.

On the details of some experiments and cases, the preceding author states, making other conclusions, the following:

1. That effusion is not an ordinary consequence of penetrating wounds.
2. That if the gut be full and the wound extensive, the surrounding pressure is overcome by the natural

action of the bowel leading to the expansion of its contents.

3. That if food has not recently been taken, and the wound amounts to a division of the gut, or nearly to the extension and contraction of the entire of the intestine, effusion.

4. That if the canal be empty at the time of its wound, no subsequent state of the bowel will cause effusion, because the supervenient inflammation affords limits to the surrounding surfaces and forms a vascularised sac; nor can effusion take place from a laceration of the intestine, provided it retains a certain portion of its elastic power, nor would any extravasated matter be a small amount of the tube, for then the extreme end contraction are too partial to prevent extravasation.

5. That when, however, air has escaped from its vessel, or food has been extravasated in quantity within the abdomen at the time of the injury, extravasation made to effusion will be less efficient, although the partial pressure is the same, as even from this source seems readily that the solids externally is common.—(P. 25, 26, 100.)

6. That though contraction is not common in penetrating wounds, a fibrous sac generally is found where the bowel is ruptured by laceration or laceration, while the fragments continue to contract.—(P. 26.)

7. That when the bowels are perforated in many places, there is more tendency to effusion than in cases of wounds.—(P. 26, 50.)

Mr. Trauer attempts to explain the reason of the greater tendency to effusion in cases of laceration and in violent laceration than in those of incision. "By the difference in the nature of the injury which the former wounds is often perforated by a sword or bone, as it is incision, or blunt or perforated, in the other. A wound or laceration could only take place under a divided state of the bowel, a condition just fit to permit effusion, and from the texture of the gut, a rupture so produced would seldom be of limited extent. The process of ulceration, by which an aperture is formed, commences in the internal coat of the bowel, which has always increased a more extensive laceration than the perforation covering. The position or position is a solution of continuity in a point or line, the wound wound is a small loss of substance. The consequence of this difference is, that while the former, if small, is closed up by the effusion from the cut vessels, it is large, is usually differentiated by the first entrance of the effusion, the latter is a permanent orifice."—(P. 40.)

How much Mr. Trauer and Mr. John Bell differ in opinion upon these latter points, will appear from the following passage: after admitting to the admission, which takes place between the viscera and the peritoneum, under a variety of circumstances already known, Mr. John Bell observes, "This is a point upon the chief difference, in point of danger, between a lacerated and a wounded intestine; for, in a wound, there is, as we should suppose, no time for adhesion, nothing to keep the parts in contact, so that by which the adhesions might be produced. But in a case where there is a point disease, laceration inflammation, adhesion, and adhesion and healing afterwards, sometimes a cicatrix remains discharging freely, and sometimes there is a perfect cure. If a particularly large wound, a laceration or very dangerous laceration be sustained, it is likely to be a wound, causing swelling and dreadful pain; in such a case, from internal pressure, and from the suppuration, the bowel comes, the gut is torn beyond all repair, and the fluids gradually issue and leak out. But where the stomach is cut with a broad wound, or a laceration, the fluid from the torn vessels issues, and the food itself, the other portions of the stomach, and the contents of the gut, &c."—(*Dissections on Wounds*, p. 321, ed. 3.) The author afterwards proceeds to explain that, in cases of penetrating wounds, the natural state of the contracting and contained parts, but no amount and equal pressure within the viscera exists, frequently leading to effusion.

Which of these propositions is most correct, I cannot presume to determine; and whether Mr. Trauer's view are deviations from what is most common, can only be decided by a comparative examination of a greater number of facts. When the direction of the wound and then not themselves of being, but the general tenor of the case on record undeniably affords a

time season to be apprehensive of extravasation. Yet, with respect to prognosis of the extravasation from other causes, circumstances may be very different. And it is not justice to say, that Mr. Thomson's opinions have received some confirmation from his (supposed) case, published by Dr. J. Chapman, of Belfast. It is a strange example of rigour of the stomach, and fatal effects of its contents into the cavity of the abdomen. The patient was a young lady, aged 18. She was suddenly taken ill with pain in her stomach, and other severe symptoms, and died in about twelve hours. "On opening the abdomen, the stomach was observed to be full of food, and empty. The intestines, among which were recognized oatmeal and cauliflower, had escaped into the cavity of the abdomen through a round aperture situated on its anterior surface at the union of the cardiac and pyloric portions. The perforation of the stomach was perfectly circular, about the size of a pea, and appeared to be the result of an ulcer on the very outer surface, which had gradually penetrated the other coats." This case was history and medical, fairly the size of a shilling, and had the appearance as if it had been made with a needle, with the needle in a cream."—*Dr. Chapman, Med. Chir. Trans.* vol. 8, p. 236.

To the preceding Mr. Thomson has attached much additional facts:—that in an instance of a rapidly fatal effusion of the intestinal contents through an ulcerated opening about a finger's breadth below the pylorus. The stomach had a perforated ulcer, and proved to be the cause of an irregular superficial ulcer of the stomach wall. Another case is that of a gastric ulcer of the great curvature, and fatal extravasation of its contents. In another instance, a vesicular eruption of the peritoneum, diagnosed by M. J. A. Brown's quill, was found after death on the junction of the stomach and intestine. It was near the centre of an ulcer that had destroyed the villi and mucous coat of the stomach in the stomach of this case. For many other instances of this kind, I must refer the reader to Mr. Thomson's paper, who concludes with remarking, that the chief diagnostic symptoms of these lesions are as follows:—

1. Swelling, tenderness, and excruciating pain, radiating from the epigastrium either to the navel, to the umbilicus, or to the trunk, and even to the back. A peculiar pain, the intensity of which, like that of peritonitis, exceeds the usual kind of the patient, who, within an hour from the enjoyment of perfect health, expresses his relief and declares himself cured, but if the pain be not speedily relieved he need die.

2. Greatness of the shock of pain, remarkable rigidity and hardness of the belly, from a fixed and spastic contraction of the abdominal muscles.

3. A lateral pain in some cases, and the symptoms are accepted as those of acute peritonitis and the first legislation in the adhesive stage.—(*Med. Chir. Trans.* vol. 8, p. 231, et seq.)

Blood is more frequently extravasated in the abdomen than any other fluid, but it does not always take place, when the vascular vessels are above a certain magnitude. The extravasation of the abdominal vessels is peculiar to each artery and vein, and is not only peculiar to each, but is also peculiar to each. The action of the vessels, which depends on the mechanical pressure and expansion, is modified very much by what happens in some cases of spasms for hours, attended with action of the arteries in contraction. If these vessels have in expansion, after being relaxed, the arteries which contract from them on any way which they receive is not full in the abdomen, but is propelled towards the right in the abdomen, and then makes its exit. The arteries, which are often from a ruptured artery, which is broken in the stomach, intestine, or even in the wall of the stomach, and in consequence of the rupture the blood is forced out with a large vessel. When the arteries are not relaxed, it is probable that the blood is not sufficient to keep the blood from pushing its way from the vessels, and it may be that it may be coming diffused among the contents of the stomach, and then the extravasation is confined to the stomach. The blood is forced out and accumulated in this way, it is forced out of the arteries and into the cavity of the abdomen, where it is forced out of the arteries, and by the side of one of the great vessels. The blood of the blood may perhaps take this action, or perhaps there may be some resistance in the direction that is shown, in

opening the bodies of persons who have died with such extravasations, things may put on a different aspect, and the blood may be found in the extravasated over every part of the abdomen. But when such bodies are examined with care, it will be found that the blood does not indicate itself among the vessels of the stomach, when the abdomen is opened, and the most previously seen is a large of pouch. This pouch is completely surrounded and limited by thick membranes, especially when the extravasation has been of some duration.—(*Schäffer, Médecine Opératoire*, t. 1, p. 29-30.)

Every practical surgeon should remember well, that all the abdominal viscera closely touch either each other or the inner surface of the peritoneum. This is one great reason why extravasation, any solution extremely diffused, but commonly for its own sake, as Pott, Schaeffer, and all the best moderns have noticed. The pressure of the elastic bowels, diaphragm, and abdominal muscles, not only constantly compresses enough to the diffusion of extravasated matter, but when nerves in proper it reaches the mouth of the wound. The records of surgery furnish numerous instances in which persons have been stabbed through the body, without fatal consequences, and sometimes without the symptoms being even severe. In Mr. Thomson's collection many cases exemplify this observation are quoted from a variety of sources: *Tab. Hæmorrh. Chir.* (Chirurgia), 5. vol. 74. *Revue de Paris*, 1840, 1841, 1842. *Wilmers' Surgery*, p. 231. *La Nouvelle France* (Chirurgie), 1840, 1841. In such cases the bowels have been supposed to have sealed the point of the wound, and perhaps in a few instances this may actually have been the fact; but in the probability of such examples, the bowels may have been severed, and the extravasation of intestinal matter prevented by the pressure of the viscera against each other.

The point or spot in which the extravasated blood or serum is, as mentioned by Schäffer, is formed by the same process which constitutes the matter of abscesses.—(*See Appendix*.) It is, in short, the adhesive inflammation. All the surfaces in contact with each other, and surrounding the extravasation, and such of the wound, gradually grow together to form a cavity, covered together by the adhesive inflammation, that the place in which the extravasation is lodged, is a cavity, usually minute of all communication with the cavity of the peritoneum. The track of the wound leads to the spot of the wound, but has no direct opening into the general cavity of the abdomen. The cavity with which the above inflammation frequently follows is small and minute.

It should be known, however, that extravasations are sometimes diffused in various degrees, and the viscera, being in the patient's body subjected to a great deal of action, are affected with violent spasmodic contractions of the peritoneum. These and also are also generally disposed to a great effect. As for blood, its diffusion is complete, and often leads to a further knowledge and confine the extravasation in one mass.

Symptoms and Treatment of Extravasation in the Abdomen. It should be known, however, that extravasations are sometimes diffused in various degrees, and the viscera, being in the patient's body subjected to a great deal of action, are affected with violent spasmodic contractions of the peritoneum. These and also are also generally disposed to a great effect. As for blood, its diffusion is complete, and often leads to a further knowledge and confine the extravasation in one mass.

In these cases, the symptoms which, perhaps, had disappeared under the employment of bleeding and emphysema, now reappear. A soft fluctuating tumour may be felt at the lower part of the abdomen.

sometimes on the right side; sometimes on the left; but occasionally on both sides. The pressure made by the effused blood on the urinary bladder, excites the irritating incitations to make water; while the pressure which the sigmoid flexure of the colon exerts in the course of ultimate evacuation. In the meantime, as the quantity of extravasated blood increases, the peritoneal influence. The pain grows weaker, debility ensues, the countenance becomes moistened with cold perspirations; and according to some writers, unless the symptoms prove so ominous for the discharge of the fluid, the patient falls a victim to the accident.

In the year 1755, Vacher adopted the same plan, though it did not answer (as is alleged), in consequence of the information having advanced too late before the operation was performed. Long before the time of Vacher and Ferri, a successful instance of similar position was recorded by Celsus, in a work which this writer gathered under the title of *Alphabeticae Medicorum, et Anatomes Elementarum accuratissime, causis frequentis, Corporis Humanus, et Morborum Methodo, et Libris, Accuratae Observationis, Observationum, Medicinae, et Chirurgiae peritiae, Graecae, 1601*. The method pursued by Vacher was therefore not so new as Petit imagined.

Indeed, when the symptoms leave no doubt of there being a large quantity of blood extravasated in the abdomen; when the patient's complaints are of every violent nature, and are evidently owing to the inflammation and pressure of the blood on the surrounding vessels; and when a local swelling denotes the seat of the extravasation, there cannot be two opinions about the propriety of making an incision for its evacuation.

Caution should be used, however, that if necessary, be made, a small extravasation of blood may not produce any considerable irritation. On the contrary, when the cyst containing the blood is opened, the air that enters, and that part of the fluid which should be discharged passes, and becomes so irritating as to be a true cause of inflammation. The last symptoms are also sometimes chiefly owing to the fatty dose in parts within the abdomen, and will more easily to inflammation within than early, arising either from the wound, than from the presence of effused blood. On the whole, I am disposed to give a late writer in the belief, that the practice of discharging extravasated blood from the abdomen can rarely be advisable. — See *Albani's Med. Surgery*, p. 412, et 21.

2. *Cysts and Purses*.—These are not so easily extravasated in the abdomen as blood, because they do not require so much resistance on the outside of the stomach and intestines by which these vessels are natural more through the alimentary canal, so blood requires to keep it in the vessels. However, when the vessel is large, and the blood effused at the point of the injury, or when, as Mr. Trautman has explained, it is extravasated in blood effused in the abdomen, which fluids are incapable of making effectual resistance to the escape of the individual matter, the latter may be effused.—(See *the Inquiry into the Process of Nature in evacuating Injuries of the Abdomen*, &c. p. 24.) Nothing is a better proof of the difficulty with which cysts and purses are extravasated, than the operation of an incision, when the stomach is wounded and full of stomach. In this instance, if the incision be the communication of the contents of the stomach were not considerable, they would be effused in the abdomen instead of being vomited up. A peculiarity is worthy of the surgeon's attention is, that the opening which allows their contents to escape, may also allow them to return into the stomach.

Extravasation of intestinal matter in the abdomen is attended with severe and dangerous symptoms; considerable pain and swelling of the belly; insupportable tenderness and heatings and vomiting, with which the patients are generally attacked the day after the receipt of the wound.—(Salutator, *Med. Operative*, t. 1, p. 24.)

In these cases, only general means can be employed; vomiting, sweat, immersions, low diet, perfumed rest, narcotics, &c. All solid food must be strictly prohibited. If patients can be borne without inconvenience, it is necessary the diet is the only support of the state of the system, may be increased by the application of a mustard raised the body.

If the symptoms are not quickly abated, the inflammation spreads over the whole cavity of the abdo-

men, gangrenous mischief takes place, and the patient dies in the course of a few days.

3. *Bleeding*.—Bleed, on account of its great facility, is more apt to be widely extravasated in the abdomen than either blood or the contents of the stomach and intestines. However, an account of the small size of the gall bladder, and its position peculiar situation, between the convex surface of the liver and upper part of the transverse arch of the colon, beyond of it is necessary.

Salutator informs us, that he has only seen this in one example on record. This case was communicated to the Royal Society of London, by Dr. Mead, — *No. 484, p. 341. Abdomen*, vol. 7, p. 371, 372. A wound penetrated the cavity of the abdomen, and entered the fundus of the gall bladder, without doing any material injury to the adjacent parts. The abdomen was immediately distended, as if the patient had been afflicted with an ascites, or hydropsis; but not the swelling either became or diminished, till the patient's death, which happened in a week.

Though there was a great deal of tension, there was no fluctuating tumor in the abdomen. No more than very little urine was discharged, notwithstanding purgatives and diuretics and a good deal of liquid evacuation was given. Analysis failed to find any remnant of solid matter, and the patient was extremely thin at his funeral state. There was no appearance of liver, and the pain was always violent till the last day of the patient's life, when it became remittent. After death, the intestines were found much distended, the gall bladder quite empty, and a large quantity of bile extravasated.

Salutator had an opportunity of viewing the symptoms of an extravasation of bile, in consequence of a wound of the gall bladder. The patient's abdomen swelled very quickly, the respiration became difficult, and he soon afterwards complained of nausea and pain in the right hypochondrium. The pulse was small, frequent, and contracted; his extremities were cold, and his countenance very pale. The tendings which were perceived the first day gave rise to a little relief, but the tension of the abdomen and the difficulty of breathing still continued. A third day after the patient fell into the lowest state of weakness, and he expired upon a protracted suffer. On the third day, the lower part of the belly was observed to be more free around, and there was no death in any sensation. Salutator introduced a trocar, and gave vent to a green, viscid fluid, which had no smell, and was just like that had escaped from the wound of the gall bladder. After the operation, the patient grew weaker and died in a few days. On opening the body, a large quantity of yellow bile was found around the peritoneum and intestines; but it had not penetrated itself nearly the communication of the vessels. A thick stratum covered the bowels evenly, and they were prodigiously distended. The gall bladder was obliterated, and almost empty. Tendons in fact, there was a wound about a half an inch long, depending on a similar wound in the peritoneum. The wound which had occurred in the nature and lower part of the right hypochondrium between the third and fourth false ribs, indicated from behind forwards, and from above downwards, between the cartilages of the ribs, until it reached the fundus of the gall bladder.

Salutator takes notice that the symptoms of the two cases, which have just now been related, were very similar. Both the patients were afflicted with a redness of the surface of the belly, tenderness and pain in the hypochondrium, and they were both extremely emaciated. Their pulse was extremely weak, the latter died of their lungs when, and they were afflicted with diarrhoea, nausea, and vomiting.

Salutator seems to think, as they certainly, in the wounds of the gall bladder, attended with the extension of bile, are absolutely mortal, and that no operation can be of any avail.—(See *Medicæ Systema*, t. 1, p. 31—37.)

A contrary instance, however, may be drawn from a case related by Pottius, in which a lady had lodged in the gall bladder two years.—(See *Observations de Pottius*, p. 255.) The recovery published by Mr. Pottius of Stamford, tends also to prove that some effusion of bile is not necessarily fatal. A lady about thirty years old, received a violent blow from one of the

shaft of a cart, on the region of the liver. The injury was succeeded by pain, frequent vomiting of bilious matter, great sinking, coldness of the extremities, and a weak, small, fluttering pulse. The belly was distended, and purging stools thrown up. On the third day, symptoms of inflammation began, attended with considerable pain about the liver, great tenderness and soreness of the abdomen, and frequent vomiting. The pulse was quick, small, and weak; the skin hot and dry; the tongue much coated; the urine high-colored; and there was some difficulty of breathing, and much thirst. Eight ounces of blood were taken today, the inflammation continued, and a few grains of calomel were directed to be given every five hours, until the bowels were properly opened. Afterward, the effluvia (exhalation), with ten drops of laudanum, was exhibited every four hours.

On the following day the patient had some motion and was much better; but, as his sickness continued, he was ordered a grain of opium every four hours. About a week afterward, he complained of a great increase of pain, which was worse than before by a shaver. He was now completely prostrated, and he could keep awake, but the vomiting, pain, and sickness were great.

Two days afterward, a discussion was perceived in the abdomen, which, in a further week, became considerably distended with fluid. The patient now did not complain of much pain, but appeared to be making little or no progress was made in the swelling, and this first period what appeared to be pain had now subsided. The uric acid then was becoming regular, and the appetite good. In the third week, the operation was repeated, and fifteen grains of the same blood were drawn off. Nine days afterward, another puncture was made, and thirteen grains more let out, and all were discharged in twelve hours. From this period the leg swelled up well, and perfectly recovered under the use of light mercurial ointment. (*See Med. Clin. Trans. vol. 3, p. 300*.)

A previous anatomical section of the gall bladder to the peritoneum might also prevent the accumulation of bile and its dangerous effects. (*Gallies, Anat. Clin. Medica, t. 1, p. 18*.)

According to Dr. Bauman, a deep wound of the liver is as fatal as if the liver itself was exposed. The slightest injuries are mortal. He claims that the same symptoms of a wound of the liver are felt from it if the vital and some symptoms of the same nature occur, and great and dangerous tenderness of the liver. The discharge from the wound is generally yellow and glutinous, except sometimes in early cases, as mentioned above. (*The Military Surgeon, vol. 2, p. 228*.) For some other interesting observations on wounds of the liver, I refer your attention to the following: (*See also the Medical and Military Reports, Jan. 1855, and the Medical and Military Reports of the Medical and Military Surgeons in Belgium, See 1855*.)

8. *Wound*.—The kind of a very fluid nature, such as the bile, is extremely offensive to the abdomen, when the bladder is wounded at any point connected with the intestines. If it is the kind of case the liver is cut down off with a catheter, so as to prevent its extrusion, the patient soon perishes. Many anatomists are of the opinion of the bladder being removed even by a deep wound, which is very mortal.

Wounds of the bladder are attended with a discharge of bloody urine and difficulty of urinating. They are always dangerous cases, both on account of the risk of the effusion of or irritating a fluid in the abdomen, and of the chance of extrusion of the bladder into the cellular membrane. Under proper treatment, however, they often admit of cure. (*See Green's Med. Medica*.) If possible, the effort should be made to be discharged by a depending posture, at suitable punctures, or injections, and the extrusion of extravasation prevented by the use of a catheter, which is to be left in the urethra. The patient must not be allowed to urinate. As the tension and pain of the body, the constant attendance of a wounded bladder, they may be greatly relieved by the use of the warm bath (chloride, t. 1, p. 713), or rather immersions, which would not require the patient to be moved; exhibiting low diet, and other antispasmodic means, not being omitted.

Wounds of the bladder.—As Dr. Bauman has ob-

served, these cases are extremely dangerous, though not generally fatal. "Bauman, Percy calculating, that of twenty cases, five or six only have escaped; this, however, is a considerable average." Two cases of the wounds of the stomach are reported by Dr. Bauman. (*See also the Medical Reports in Belgium, &c.*) With respect to the chances of recovery, Dr. Bauman justly remarks, that the frequency of the bladder, Perizon (Dr. Bauman's *Colic*—*Perizon*, *Revue Méd. 1855*), and English "Colic" cases," in some of whom the kidneys have been cut out, and in others discharged spontaneously through the coats of the stomach and portions of the bladder, are very encouraging. In France, a silver fork was found, embedded three or four inches in the stomach, by Mr. Renault, of Rouen, in the department of the Orne, who performed gastrostomy for the purpose with complete success. (*See Quarterly Journal of Med. Sci. 15, p. 321*.) He has collected many instances of recovery, both from natural and artificial wounds of the stomach. (*See also the Medical Reports in Belgium, &c.*) But according to Dr. Bauman, the results in the articles "Ventricular" and "Perizon," have brought together the largest number of cases. Dr. Bauman refers to *Laennec's Abdomen of the Stomach*, vol. 6, p. 192, for instance, in which the stomach of a female was ruptured and sewed up, and the same practice extended in the female subject with success. It appears, also, from the *Journal de Médecine*, &c. t. 2, by Krieger, from Bauman's *Transplantation*, and the *Journal de Médecine*, &c. t. 2, p. 300, that wounds of the stomach have been attended with success in various cases of emergency. (*See Bauman's Military Surgeon, &c. p. 438*.) As the latter author observes, wounds of the stomach are not accompanied by hemorrhages, and remain open. In a case recorded by Bauman, the fluids contained upon them freely, and in a severe instance, noticed by Bauman, ten years. (*See Bauman's Medical Progress, &c. p. 330*.) And Weisley has detailed a case, in which the opening continued freely seven years. (*See Bauman's Medical Progress, &c. p. 330*.) For further information connected with this subject, the reader may also consult *Journal de Médecine*, &c. t. 2, p. 300, and *Journal de Médecine*, &c. t. 2, p. 300.

Wounds of the Intestines.—The rupture of blood in the large of it by itself; the escape of fluid also is of a fatal nature from the wounds of the stomach; any simple, compound, or a portion of blood, protruding at the opening in the skin, and the stomach is exposed to the risk of a wound of the liver. When the wound is exposed in the abdominal cavity, it is obvious to the surgeon's eye; but when it is about a part of the intestine, it is not within the abdomen, the danger of the case can be known only by a consideration of other symptoms. In addition to what I have already described, there are some others which ordinarily accompany wounds of the bowels; as, for instance, symptoms about the peritonitis, some or greater pain in the belly, some events, &c. But unless the wounded intestine protrude, there is no practical good in knowing whether the bowels are injured or not; since, if it be in the abdomen, the fluids are sought not to be removed from the body, and a simple penetrating wound of the bowels, attended with a wound of any of the viscera. Large wounds of the small intestine, particularly of the duodenum and jejunum, are attended with some fever, vomiting, pain, and the continuance of symptoms, cold prostration, a small, insensating, tremulous pulse, and they frequently prove fatal. Rupture of the small intestine may also occur when the rupture of the large intestine followed by extravasation. A fatal division of the upper part of the intestine (stomach), towards the pylorus, will deprive the body of the nourishment requisite for its support. If the chyle escape from the wound, the patient will die of a short duration; and if it become extravasated, it will be likely to cause such irritation as will prove fatal. The escape of extravasated or fluid from the wound, and cause an injury of some of the large intestines. In these cases, the symptoms are generally similar, and the passage of the intestinal contents towards, through the wound, may stop, or prevent of the bowels being irreparable. If the same wound, the wounded intestine may, finally contract, as indicated in the adjacent

(P. 124.) And among other observations, I find "marked dissension of a most distinct of the usual air, irregularity, and therefore certainly fatal!"—(P. 123.)

These differences do not appear to me satisfactorily explained. We are told, that exposure to a pure air, in fact, is, in theory, more beneficial to the lungs as compared to air, and that the absolute contact of the divided surfaces, at these extreme considerations, is requisite to secure the blood from the danger of additional coagulation. The foundation of these unqualified conclusions is two experiments made on dogs; in that of which experiments, the divided lower was brought together with one stick, on Mr. John Bell's plan, while, in another, three sticks were made; and yet, in all these instances the animals died with the purports of the lungs cleared. As for the inference, more established, that animals die, for their inability, however, Mr. Verres is completely afterwards proved to refute other experiments, instituted by Dr. Asch Cooper, Dr. Thompson, and Dr. Smith, which, though Mr. Traverser seems unaware of the fact, tend most completely to overturn the conclusions which he had been previously making.

Dr. A. Cooper repeated the experiments of Henslow, who had succeeded in saving, by suturing the divided surface of a dog, including in his position of the trachea a call. In place of the undivided surface, three distinct sticks were inserted. On the sixth or seventh day the animal was killed, and the union was complete.—(P. 123.)

There are two facts, proving that a wounded surface may be healed, though the suture was not such as to rejoin the divided surface, in contact in the whole of its circumference.

Dr. Asch Cooper then made the experiment, without including the foreign substance. The animal recovered, being a third that remains; it proves, that the absolute contact of every point of the ends of divided vessel is not essential to the cure.—(See Dr. Cooper on *Spinal and Crural Aneurysm*, Chap. 2.)

After dividing the trachea of a dog, Dr. John Thompson, of Mississippi, applied five interrupted stitches, at equal intervals, the ends of the trachea were cut off, and the external wound was closed with a suture. This animal did not die of the operation, and when he was afterwards killed, it appeared that the threads had made their way into the lumen of the tracheal canal. Dr. Thompson repeated this experiment, and did not die the animal all six weeks afterward, when the same tendency of ligaments to pass into the vessels and to this discharge was manifested.

These facts are made first in good that the absolute contact of every part of the ends of a divided vessel is not essential to perfect union, or the consequence of the wound from proving fatal, and several other experiments were made by Dr. Smith, at Philadelphia, who employed four stitches with similar success.

As far then as the supposition of such facts ought to have weight, we are bound to receive the conclusions of Mr. Traverser to be correct and unimpeachable. I am surprised that Mr. Traverser himself has not described the particulars of all these last experiments, did we possess that they struck directly at his own inference. They are not only completely arguments against Mr. Traverser's conclusion, that the union of a divided vessel requires the contact of the cut extremities in their entire circumference; but they are a plain denial of another position, advanced by this author, viz. that wounds extending to a direct division of the canal are irreparable, and therefore inevitably fatal.

With respect to the species of suture being of secondary importance, provided it rejoin the circumference of every part of the divided ends of the divided vessel, I repeat that Mr. Traverser has suggested to facilitate experiments, in order to prove that exposure nature can be practised, and if he has the humanity to apply it, whether his plan would be for or against the conclusion which he has formed. The fact of the suture always making their way into the cavity of the vessel, and being thus put in of, appears to me highly interesting, since it shows the ability of calling away the ends, instead of leaving them, forming out of the external wound, as so to create the most instant and interference of sutureless adhesions. It seems that Mr. Benjamin Bell had observed that the

ends of the ligaments away, and reducing the level of the suture into the adhesion, as he says, a substantial part of the circumference of the ligament was left in the cavity of the gap.—(*System of Surgery*, vol. 2, p. 126, ed. 7.) We have seen that the experiments of Dr. Thompson confirm the observation, and were instituted by Mr. Traverser to lead to the same conclusion.

According to the latter writer, the following is the process by which a divided vessel is healed when suture is employed. "It commences with the re-approximation of the contiguous mucous surfaces, produced by the contraction of a fluid vessel to that which was torn together the ends of a recent blood vessel, when exposed to contact." The adhesive inflammation, which comes down the external edge of the exposed coat, from the whole circumference is a thick layer of coagulable lymph is effused, so as to rejoin the wounded vessel. The action of the lymphatic fibres, being exposed to the external circulation, the sections mutually rejoin, by the action of the process of osmotic absorption. During this time the lymphatic vessels become occupied by white as the function is performed, and the internal opening with the fibrils attached to it, is completed by the next time.

The putrefaction at the point of the ligament, and then fall with its end. The ligament left by the operation is gradually healed up, but the upper and lower surfaces, so far as my observations can observe, do not become consolidated by granulation, within the intervals making the division permanent, it is only scars obliterated.—(*Traverser on Surgery*, p. 126.)

Notwithstanding I have carefully read all the experiments added by Mr. Traverser in favor of suturing a divided vessel in a very young animal, and in a few weeks recovered, of the advantage of such process, for instant already suggested. It is not with a person well to me, in which a better price is than, provided, I should slightly a single case, even with a small vessel, and a patient of the age. If the vessel were completely cut, I should have no objection to amputate it, and to expose by suture, in three stitches of the same kind. I would not Mr. Traverser, respecting the advantage of suturing the ends of the ligament instead of leaving them in the wound, so I believe he is right in regard to the conclusion, there is of the injured vessel, and in regard to the wound; and that the ends of the vessel, and that of no use in keeping the wound in the wound, they must be irreparable, and therefore fatal.

On referring, some of the foregoing observations, I would refer to the valuable writings of Dr. Cooper and those of Dr. Henslow. The treatment of the wound, in which I allude, being continued in the last volume of the *First Lines of Surgery*, and in the *Medical*. The only gratification (says Dr. Henslow) is that, such severe loss having no other result than the loss of a few inches of the vessel, although the patient's employment of suture ought to have been more than how much she could bear with impunity. The chances are very little doubt that their ability, provided, if not positively harmful. In the course of a case, extensive suture, was once only have some, and, of course, suture was required to a considerable length, though frequently it may be needed for the suture of the patient.—(*The Medical Surgery*, ed. 2, p. 411.)

When the protruded intestine was found, which was very rare occurrence, it was of course, no doubt, should be the same as that of a small intestine.—(*See Henslow*.)

As Dr. Henslow observes, in the treatment of wounds of the abdomen, the value of suture is to be maintained more by general means than by any of the surgical aids of surgery. The search for suture is being, in fact, especially in the case of the case, to be such a good, is entirely out of the question. Entailment of infection of the wound, as the case may require, for retaining protruded intestine, is a very serious matter, and promoting its return to the part, is all that the surgeon need do in the way of operation, and even in this the best is suture of the vessel.—(*On Medical Surgery*, ed. 2, p. 411.)

The principal indication is to prevent a dangerous degree of inflammation. Hence bleeding and the antiseptic characters are highly indicated. The

the surgeon be deterred from such practice by the apparent debility of the patient, his small, concentrated pulse, and the coldness of his extremities; symptoms common to severe inflammation of the bowels, and, in fact, themselves indicating the propriety of repeated venesection. Wounds of the small intestine are attended with more dangerous symptoms than those of the large ones. All diet, stimulants, and solid food is to be prohibited. The bowels are to be daily emptied with opium, by which means no matter will be suffered to accumulate in the intestinal canal, so as to excite inflammation and distension.

When extraneous matter is discharged from the outer wound, it is highly necessary to clean and dress the part very frequently. Gentle pressure should also be made with the finger, at the circumference of the wound, in order to apply the pressure of any extravasated matter. For the same reason the patient should always lie, if convenient, in a posture that will render the wound opening depending.

After a day or two the surgeon need not be afraid of letting the outer wound heal up; for the adhesive is, from its situation, at a distance from the course of the wound, will have passed any extravasation, either from haemorrhage diffused among the viscera. If the case should run well, the intestine gradually indurates a distention is its diameter in the place where the wound was situated. When this contraction is considerable, the patient occasionally experiences colic pains at the part, especially after eating solid food as tends to produce flatulence. As these pains usually go entirely off after a certain time, and to ineffectualness whatever remedy, the intestine may possibly regain its wonted capacity again. A more considerable contraction of the above sort has been known to occasion a fatal outcome. Even the intestine itself has been known to heal in this situation, after it contained food ascertained beyond the contracted part. Patients, when recovered from the wound in the intestine, should exercise and be particularly careful not to swallow any food substance, or indigestible dissolved food. On this subject the writings of Scarpa are particularly interesting.

In some instances intestinal matter continues to be discharged from the outer wound, either in part or entirely, so that either a fistula or an artificial anus is the consequence. A fistula is more apt to follow when an intestine has been injured by a ball, has been quite cut through, or has mortified. But numerous cases prove that this is not invariably the consequence, and that a perfect cure has frequently followed each of these occurrences.—(See *Acute, Artificial*.)

When inflammation is completely cut through, and the lower portion of the canal has successfully contracted in the abdomen, writers insist upon the necessity of preserving the formation of an artificial anus. In this particular case they recommend filling the extremity of the intestine with a fine suture in the edge of the outer wound. In order to distinguish the upper end of the intestine from the lower, the proposal is sometimes made to give the patient a little wine, and to observe whether the fluid, after a time, issues from the mouth of the protruded gut. In the mean while fumigations are employed. If the upper end of the intestine be in the abdomen, these fumigations seldom even form a junction, when the excision is quite recent, to dilate the outer wound, means for the better continuation of the bowel, and then are the two ends right.

Practical surgeons, however, are right in withholding life support in such situations.—Indeed says a modern writer, the surgeon would have long since discovered their fears about the intestine falling upwards, and about the difficulties of distinguishing between the right and the wrong end of it. The operations of abdominal effusions are fearful pretty well settled. The reference is extremely rare, and when it does happen, we leave the poor wretch to die in pain, without searching after effused fluids, the nature of which cannot be known, or, if known, the inflammation caused, in the most remote degree, lead to recovery. I have never witnessed a case where any possible good effect could follow the paracentesis in peritonitis, it is more expedient then, has always preceded the symptoms, which would lead to the performance of that operation.—(Hewson on Military Surgery, vol. 2, p. 411.)

In some instances matter falls into the abdo-

men, lodge there a considerable time, and are then washed through the intestinal canal; while in other instances they become organized, and continue lodged the rest of the patient's life, without producing much, or indeed any inconvenience.

Gasotomies and other injuries of the abdomen.—A violent contusion of the abdomen may happen in contused wounds, without the occurrence of any external wound. It was in this way that the liver or gall bladder was ruptured in the way mentioned by Mr. Potts (Med. Chir. Trans. vol. 4); and thus the virus was introduced in the case which fell under the observation of Richman, where a man whilst passing a child's belly.—(Necropsy Chap. I. N. p. 385.) In other instances the violence is done to the intestines, and still more frequently to the viscera, as well as the parietes of the abdomen, have only suffered a shock or been bruised externally. The effects of such violence are inflammation of the injured viscera, and their adhesion to the walls of the peritoneum. Then, the stomach and intestines, the liver, and the gall bladder, when detached from a focus upon the front of the belly, come in contact with the corresponding portion of the parietes, which has been also bruised, and is thus inflamed. When such inflammation suppurates and, according to Richman, it is their most usual course, opening the abdomen, the pus is found blended with the matter which the viscera contain elsewhere. Thus the alimentary canal, and even intestinal contents, have been discharged with the pus on opening, contain a mass which communicated with the cavity of the stomach or bowels, and has been found blended with the matter of abscesses in the right hypochondrium.

When, in consequence of a blow upon the anterior part of the belly, the patient experiences the situation of the injury a deeply-seated pain; when a tumour forms, and the symptoms indicate violence done to some of the abdominal viscera, the inflammation is to be opposed by every possible antiphlogistic means. But when, notwithstanding such treatment, the swelling increases and suppurates, the abscess is not to be opened until it is perfectly mature. The inflammatory symptoms, which precede its formation, indicate that there is an adhesion between the injured organ and the parietes of the abdomen. Without this adhesion, opening the abscess would be attended with more harm, because the pus or other matter might become extravasated in the cavity of the peritoneum. For the same reason, in the examples of tumors caused by life in the gall bladder, J. L. Pott recommends deferring the operation of opening them, until the inflammatory symptoms evince that an adhesion has taken place between the fundus of the gall bladder and the corresponding point of the parietes of the abdomen.

An abscess of the abdominal viscera to the inner surface of the peritoneum may be induced by other causes besides the action of cooling bodies. A knife, a fork, a shoemaker's awl, a needle, and other extraneous substances incapable of passing through the alimentary canal, have been known to irritate the stomach or bowels, and to bring on adhesion of them to the parietes of the abdomen, where a burrow has formed, which, on being opened, has discharged the foreign body. The records of surgery abound in facts of this kind. A fistula records the opening of the abscess, the alimentary matter escapes, and, if the aperture itself had not been healed by methodical compression, the intestine, canal between the bowels and the anus remains; most of the contents of the bowels pass out at the preternatural opening, and the patient falls into a state of inanition, the anus gradually fatal, the greater the injury of the intestinal canal, it is the sicker.

A long-continued pressure on the epigastric region may cause an adhesion of the stomach to the parietes, and suppuration taking place at the part, a fistula, communicating with the cavity of that organ, is formed, and allow the contents to escape externally.—(See *Histology, Physiology, &c. of the Digestive System*, Chap. 2, p. 323-326, edit. 4.)

I shall conclude with repeating, that in the proximity of rupture of the abdomen from internal violence, of rupture of the stomach or colon, the principal danger whether towards or contraindication of the peritoneum, in depends upon inflammation of the peritoneum. In the treatment, therefore the most necessary thing is to

rated, Mr. R. Bell conceived that it was attended with hazard of wounding the large blood-vessels. Although it seems to me better to use a vaso-vital history, it is a difference than the kind of reason which Mr. Sharp employed, I do not coincide with Mr. R. Bell in thinking that the latter surgeon's plan was at all objectionable, or the source of danger in respect to wounding the vessels. Some practitioners may even think Mr. R. Bell's method most likely to injure the large vessels; for he advises the operator to cut the muscle five or six gradually towards, as deeply as necessary.

Perhaps the most modest method of operating, is to divide the vertical portion of the contracted muscle near the clavicle, and even to cut out a sufficient piece to remove all chance of the two ends uniting again. This may weaken the muscle considerably, and perhaps might answer every purpose. It might easily be accomplished by means of a director and curved bistoury, after making the requisite division of the skin with a common scalpel. Were this proceeding to produce only partial anastomosis, the normal portion of the muscle might afterward be divided. A director should be passed under it, and the division made with a probe-pointed curved bistoury. In operating on a female patient, it might be advisable, with the view of avoiding a large scar, to make only a puncture, and pass the knife *dissecto-wards* and close behind the vertical portion of the muscle, the posterior part of which could be divided by then turning the edge of the instrument *verso-wards*. In this manner, Dupuytren operated successfully in one instance.—(*See Quarterly Journal of Foreign Med. etc.* 20, p. 532.)

Any cause destroying the equilibrium between the sterno-clide-mammaric muscles, will produce a wry-neck. Thus, when one of them is affected with spasm, and acts more forcibly than the other, it draws the head towards the shoulder of its own side; but when one sterno-clide-mammaric is paralyzed, while the other retains only its natural power, the balance of action is equally destroyed, and the head is inclined the head towards the opposite shoulder. In paralytic cases, electricity (Phil. Trans., vol. 68, p. 52; Gally in *London Med. Journ.*, vol. 4, 1799; Wilson, stimulating liniments, the shower-bath, sea-bathing, warm, arsenic, the application of moxa, and anæsthesia to the health in general, are the means affording the best chances of relief.

Although the dry-season sometimes depends on the state of the storm-cloud-mountainous weather, it is frequently owing to a sheering of the isotherms. Local winds successfully divided contractions of the air, which had kept the local dryer to one side for many years, and had been connected by lanes. Some of these contractions, the size, might easily have been mistaken for a part of the storm-cloud-mountainous itself.

Mr. Gooch relates a case of very much, which was caused by a contraction of the platysma myoides muscle. The patient was a young gentleman fourteen years of age, who had always enjoyed very good health in every other respect. For several months the head had been strongly drawn to one side by a constant contraction of the platysma myoides muscle, which was exceedingly rapid, especially about its insertion at the base of the jaw; and from the angle of the os maxillare inferior to the chin the skin presented an appearance like that of the skin of a lion. The same side of the face, quite from the point of the chin, was much shrunk and distorted by the contraction of the zygomatic, and the corner of the mouth in particular was so drawn to one side and downwards when the patient closed his head, that a vast deal of deformity was the consequence. From the inferior part of the eyebrow, at the internal angle of the eye to near the tip of the nose, there was a kind of furrow upon the skin about half an inch broad, with a shining, polished appearance, like the process of a wound, and devoid of hair, which had fallen off. From the corner of the eye downwards, there was the same kind of appearance in a less degree. The patient was subjected to repeated attacks of spasms, which began at the insertion of the muscle, and terminated at the eye, attended with a prodigious pain. The ear, and also the temporal and frontal muscles, were sometimes affected in a similar manner. The parts in the course of the insertion of the muscle into the jawbone, were considerably thickened, without being in the least inflamed.

externally, and when bunched, but not stretched, they were quite painful. The subjacent muscles did not seem at all affected.

It appears from the account given by Mr. Goodrich, that in the treatment of this affection, *crura* *anagae* muscles had been used, by the advice of the best em-
pirical practitioners; but without effect. Mr. Goodrich
attributed to my visit benefit would be produced by ex-
tension of the muscle. He first divided the lateral
muscle a little below the joint, and then exposed the
whole breadth of the *genua* *anagae* muscle, the
fibres of which seemed to be in a state of violent ex-
tension, especially when the patient's limb was in-
tended towards the opposite side. Mr. Goodrich then
divided the muscle completely across, in a very careful
direction, until the fibres of the *anagae* *anagae* muscles
were exposed. The patient was then directed to turn
his limb towards the opposite side, and Mr. Goodrich had
the satisfaction of observing, that the patient could
perform this motion, without the least degree of the
muscle being affected, as they lay perfectly to be.
The wound was treated in the ordinary way, and no
particular symptoms arose. As soon as the inflam-
mation had subsided, the patient was directed to
perform the same motion, in order to prevent any
kind of stiffness which might arise from the con-
striction of the muscular fibres, and the elasticity of
the tissue.

The patient was perfectly relieved by the foregoing operation, and had no return of the painful spasms, to which he had been previously subject. The side of his face, however, never resumed its proper degree of distension.—*Chir. Med.*, vol. 8, *Case*, &c.

have lately seen an elderly gentleman, who is afflicted with a varicocoe, for which several of the most eminent surgeons have been consulted; but they have not advised an operation, nor have any of their prescriptions been of service. The case is complicated with a constant tremulous motion of the testis, and great weakness and indolence of the upper extremities, so that the patient cannot get a glass or cup to his mouth, without using both hands for the purpose.

Whenever an attempt is made to cure a very thick, by dividing any of the sinuities, or merely the integuments, it becomes necessary to take special measures for keeping the head in a proper position, during the treatment of the abscess; first, in consequence of the head inclining in the direction in which it was before the operation, the divided parts should grow together again, and bring the patient into the same condition in which he was before any thing had been done. With a view of preventing this unpleasant circumstance, Mr. Simpson recommends fitting the wound with flax, and making it suppurate. Mr. R. Bell, on the other hand, advises the employment of a proper machine for keeping the head in a due position. Some writers make the use of a bandage sufficient for the purpose. In Bagnard's case, the cut edges of the muscle were kept together by depressing the scapula, and inclining the head to the opposite side. The first object was fulfilled by bowing the hand on the same side as the operation firmly to the face, the lower being bent; the last, by means of a roller applied round the head, and under the scapula the opposite side.—(*See Quarterly Journal of Farquhar* (Vol. II. 20. p. 423.) Sometimes, the removal of a great portion of the affected muscle is up to extremity in the operation.

Boys met with a paraisis of the extensor muscles of the hand, attended with a downward approximation of the skin to the stumps. Two cases related every point of treatment, and an apparatus for supporting the hand was the only thing tested of any use.—*Ann. du Mus. Nat. Hist. Nat.*, t. 7, p. 81, Paris, 1803.

Soc.*, 1823.

Z

ZIN

ZIN

ZINC. The preparations of this metal are of considerable use in surgery. With respect to the sulphate of zinc, it may be said to be generally the best remedy in cases where it is desirable to keep the skin moist without the least drying, as in cases of poisoning for which purpose, the common dose is ʒj. As an external application, this salt dissolved in rose water, in the proportion of gr. iiii. to ʒj. of rose water, serves as a perfect collyrium in the latter stage of ophthalmia, after the inflammatory action has subsided: it is a good injection in the earlier stage of gonorrhoea, and is useful in some kinds of superficial inflammation. Of double strength, this solution is the best application

that can be used in scrofulous sores, after they have suppurated, and the abscess has been discharged.—*Ed. V. Thomson, London Dispensatory, vol. 2, p. 269.* A simple ointment of zinc is often serviceable for abatement of the itching, hæmorrhoids, or itching of the Zæni ulcers. ʒj. Aq. roseæ ʒvj. (Galenus 3). M. ii. gargle with frequent strains. The sapientia ointment, composed of an ounce of the oil of fish, and six ounces of prepared lard is a good ointment, highly stimulant, drying, and is frequently employed in various cutaneous diseases, eruptions, sore nipples, and chronic inflammation of the scapularia of the eyelids.

SAMUEL COOPER,

EMBRACING ALL THE VALUABLE IMPROVEMENTS OF THE SEVENTH AND
LATEST EDITION OF THE AUTHOR, PUBLISHED IN 1838,

TOGETHER WITH

ALL THE RECENT IMPROVEMENTS IN EUROPE SINCE THAT DATE, AND A REC-
ORD OF THE REMARKABLE OPERATIONS PERFORMED BY

AMERICAN SURGEONS

IN VARIOUS PARTS OF THE UNITED STATES; THUS BRINGING THE
SCIENCE DOWN TO THE PRESENT TIME.

BY DAVID MEREDITH REESE, A.M., M.D.,

PROFESSOR OF THE THEORY AND PRACTICE OF PHYSIC, AND OF THE PRINCIPLES OF SURGERY IN VER-
MONT MEDICAL COLLEGE, VERMONT; AND PROFESSOR OF THE INSTITUTE OF MEDICINE AND
MEDICAL JURISPRUDENCE IN THE WASHINGTON UNIVERSITY OF BALTIMORE; HONORARY
MEMBER OF THE MEDICAL AND CHIRURGICAL FACULTY OF MARYLAND; MEMBER
OF THE MEDICAL SOCIETIES OF MARYLAND AND NEW-YORK, &c., &c.

NEW-YORK:

PUBLISHED BY HARPER & BROTHERS,

NO. 82 CLIFF-STREET.

1844.

Entered, according to Act of Congress, in the year 1812, by
HARRIS & BROTHERS,
in the Clerk's Office of the Southern District of New-York.

ALPHABETICAL LIST OF AMERICAN SURGEONS

WHOSE OPERATIONS OR CONTRIBUTIONS TO SURGERY ARE REFERRED TO EITHER IN THE BODY, OR THE APPENDIX BY THE AMERICAN EDITOR.

- J. H. Arnold, M.D., of Albany.
 John Arnott, M.D., of Baltimore.
Richard Bagley, M.D., of New-York.
 J. Bellinger, M.D., of Philadelphia.
 Gordon Beck, M.D., of New-York.
George Beck, M.D., of New-York.
 Stephen Brown, M.D., of New-York.
 G. S. Bedford, M.D., of New-York.
 J. M. Bush, M.D., of Lexington, Ky.
 J. Rhia Barton, M.D., of Philadelphia.
 J. C. Choseman, M.D., of New-York.
 J. M. Carnochan, M.D., of New-York.
 A. L. Cox, M.D., of New-York.
 R. Cress, M.D., of Philadelphia.
 B. H. Coates, M.D., of Philadelphia.
 J. Cocks, M.D., of Baltimore.
 S. H. Cooke, M.D., of Baltimore.
 Josh. J. Cohen, M.D., of Baltimore.
 William Detmold, M.D., of New-York.
 E. Dinsfeld, M.D., of New-York.
 J. Depuyre, M.D., of New-York.
 E. H. Dixon, M.D., of New-York.
 J. S. Denny, M.D., of Philadelphia.
 J. H. Dix, M.D., of Boston.
 ——— Davenport, M.D., of Boston.
 J. B. Dewees, M.D., of Baltimore.
 S. H. Dickson, M.D., of Charleston, S. C.
 E. W. Doolley, M.D., of Lexington, Ky.
 L. A. Dugas, M.D., of Augusta, Geo.
 P. F. Eve, M.D., of Augusta, Geo.
 Elliston, M.D., of Augusta, Geo.
 J. W. Francis, M.D., of New-York.
 George Fox, M.D., of Philadelphia.

The additional notes heretofore found in the Supplementary Appendix in former American editions, are now inserted in their alphabetical order with the matter of the Appendix in the present new American edition.

PREFACE.

IN the article "Surgery" in the former edition of this Dictionary, and which, from the necessity of the case, is still retained in the text, it will be seen that, actuated by a national feeling, which will be appreciated by every American, I complained of the omission of the just claims and sterling merits in this department to which the surgeons of the United States were entitled, and attempted, in my notes, to supply the author's lack of service. Mr. Cooper has responded in a manner so creditable to himself, and to the liberal profession of which he is a veteran, that in justice to him I here insert his response. In the preface to his last London edition, 1838, he says,

"In particular, it affords me peculiar gratification to have had an opportunity, in this seventh edition, of bringing under the notice of British surgeons the meritorious transactions of their brethren in the United States, where the same zeal for the advancement of Surgery, and the same just estimate of its value to society, are exemplified as in the mother-country. In Operative Surgery, the surgeons of no nation have exceeded them in decision, coolness, enterprise, and boldness; and however doubtful I may individually be respecting the real good likely, on the whole, to result to mankind from certain extraordinary achievements with the scalpel, which, as will be seen in the course of this work, have been performed in America, I give the surgeons of the United States, as I do to many surgeons in my own country, France, and Germany, who are smitten with the love of similar proceedings, the credit of being actuated by the zealous hope of being able, by such means, to extend the efficiency of Surgery to cases of the most desperate kind."

"This edition will not only be the means of diffusing the knowledge of what has been done in operative and other parts of Surgery by European and American surgeons, but it will prove that, however right Dr. Reese may have been in complaining of my not having formerly done full justice to the surgeons of the United States, it was not from any desire on my part to keep their transactions concealed, but simply from the fact that I did not then possess the information that has since reached me of their praiseworthy exertions."

Under the article "Jaw-bones, amputation of," he thus speaks:

"The operation of removing a considerable portion of the lower jaw-bone is stated by Dr. Reese to have been first performed by Dr. Valentine Mott. This claim I was not aware of at the time when the article *Bones, Excision of*, was delivered to the printer, nor have I, at the present moment, leisure to ascertain the point. 'Dr. Mott is not only the first,' says Dr. Reese, 'but the only surgeon who has amputated the bone successfully at the articulation, except (since) Dr. Chasack of Dublin.' (See Amer. ed. of this Dict.)"

"I am very glad to have had this opportunity of recording the claim of Dr. Valentine Mott to the merit of having first removed the lower jaw at the articulation. The achievements of this distinguished surgeon, to whom I had the gratification of being introduced when he lately visited University College Hospital, I shall always be as proud of noticing as if they were the performances of any British practitioner."

And appended to the article "Surgery" I find the following frank and manly paragraph:

"I regret that, in the last edition, due justice was not done to the meritorious surgeons of the United States of America. This happened, however, not from any want of desire on my part to pay the tribute of honour where it was deserved, but from my not being then in possession of the valuable information respecting the progress of Surgery in the United States, which I have since obtained from Dr. Reese's American edition of this Dictionary, and other sources. I most cordially join, then, in the observation that, in a history of this kind, mention ought to be made of 'the names of Drs. White, Dudley, Davidge, Dorsey, Shippen, Bard, Post, Mott, Gibson, Parrish, Barnes, McClellan, Stearns, Warren, Smith, Jamieson, and a host of others, who have contributed by the pen and the knife to elevate this department of the profession: this will be admitted, unless the successful ligature of the subclavia, the common iliac, the internal iliac, and that of the innominate, the amputation of the hip-joint, and upper and lower jaw, the extirpation of the parotid gland, the excision of the clavicle, and the cure of aneurism, by tying on the distal side of the tumour, be unworthy of record. Some of these operations,' continues Dr. Reese, 'had never been attempted in Europe till our surgeons had led the way; and by these, and other splendid achievements in Operative Surgery, had demonstrated their practicability and success.' In alluding to such merit in the surgeons of the United States, I feel all that heartish pleasure which arises from the remembrance of their close connexion with my native country by the ties of blood and language, and they may rest assured of my sincere esteem, and of my earnest wish to render full justice to them on every subject."

It is a source of gratification to me that my humble effort has been successful in acquainting our professional brethren in Europe with the real merits of my own countrymen, so many of whom have distinguished themselves by their exertions in behalf of science and humanity, and whose meritorious claims in surgery have never before been recognised or acknowledged. Mr. Cooper has, in this seventh edition of his work, incorporated all my numerous notes and additions on American Surgery, so that our national pretensions are now spread before the profession in Great Britain. A similar mood of justice has also been since awarded us in France; for in the second edition of Velpeau's "*Nouveaux Elements de Medecin Operatoire*," the author has manifested a commendable spirit of liberality and justice to American surgery which does him honour.

The following extract of a letter lately received from the venerable author of this Dictionary, addressed to the American editor of his work, will be gratifying to the profession, and its insertion here is due to Mr. Cooper.

"Woburn Place, Russell Square, London.

"I am glad to hear that you are about to undertake another American edition of the Dictionary of Practical Surgery, for you acquitted yourself so ably in the editorship of the former one, that not a doubt can be entertained about your very superior qualifications for the task. I know that numerous valuable observations and improvements in Surgery have been made in Europe and America subsequently to the publication of your first edition, and especially since the year 1830, when your notes were written. Perhaps in the last ten years, I may say with truth that Surgery has made greater progress than in any preceding space of time of the same length; hence there must be a necessity for much change in every general treatise on the subject, in order to

adapt it to the present state of the science, and to let it give a correct explanation of the theory and practice most approved of in those parts of the world where our noble profession is cultivated with the greatest degree of success. These remarks are especially applicable to the Dictionary of Surgery, which embraces the whole range of the subject, and, perhaps, has a more extensive circulation than any other book devoted to it. Into your new edition you will be able to bring not only all the new matter brought into my last edition, but other observations and improvements made by the talented surgeons of the United States, and either not known to me, or not within my reach at the period when I was writing. Whenever I arrive at a new edition again, your testimonials of the contributions of your distinguished countrymen will not be overlooked, and every endeavour will be made to do them justice. Believe me that I shall be most happy to shake hands with you in London, and that I am most faithfully yours,

SAMUEL COOPER.

"Professor Reese, New-York."

In the present Appendix, which is all that I am enabled to add in issuing the new edition, my aim has been to avail myself of the new matter furnished by Mr. Cooper concerning transatlantic Surgery, and at the same time exhibit the improvements in Surgery which have been made in the Old and in the New World since his latest edition, which, it will be seen, are neither few nor inconsiderable. To name but a single example, the entire specialty of Orthopædic Surgery has been added, this department having but dawned when that edition was issued. And, moreover, by attempting the record of the achievements of American surgeons, especially since my last edition in 1830, I have endeavoured to bring down the science of Surgery to the present date. My limited space has imposed the necessity of greater condensation than is consistent with good taste, and in some cases may have prevented me from doing full justice to the individuals concerned. Indeed, if I could have had greater space for amplification on some topics, the performance of my task would have been much more agreeable to my own inclinations. Under the circumstances, however, I have done what I could, and trust that the candour of my professional brethren will award me all that I claim, a disposition to do equal and exact justice to all, and to exhibit the individual claims of American surgeons with impartiality and truth.

THE AMERICAN EDITOR.

P.S. The most important improvements of Mr. Cooper's last edition, including new articles superadded and old ones rewritten, have been inserted entire in this Appendix, as well as a summary of everything which he has furnished either recent or valuable in transatlantic Surgery. All such improvements will be found designated by being included in brackets, with the initials of the author appended.

K K

SUPPLEMENT.

ABDOMEN.

[**ABDOMEN.** **THE BELLY.** If the pelvis be reckoned as part of the abdomen, the latter may be said to extend from the diaphragm, which forms its upper boundary, down to the levatores ani, and from the transverse muscles in front, to the spine, quadratus lumborum, and iliac crest behind. Thus comprehensively viewed, the abdomen appears to contain and protect all the organs of digestion situated below the oesophagus, together with the urinary and internal organs of generation.

The epigastric region contains the middle part and the pyloric extremity of the stomach, the left lobe of the liver, the hepatic vessels, the lobulus papillæ, the pancreas, the celiac axis, the renal ganglia, the aorta, the vena cava, and the crura of the diaphragm. The left hypochondrium contains the large end of the stomach, the spleen and narrow extremity of the pancreas, part of the colon, the renal capsule, and the upper portion of the kidney. The right hypochondrium contains the right lobe of the liver, the gall-bladder, part of the stomach, some of the ascending colon, the renal capsule, and upper portion of the kidney. The right lumbar region contains the ascending colon, the lower half of the kidney, and part of the jejunum. The left contains the ascending colon, the lower half of the kidney, and part of the jejunum. In the hypogastric region are the convolutions of the ileum, the bladder in children, and in adults both the bladder and the uterus, if distended. The right iliac fossa contains the caecum, the iliac, and spermatic vessels, and the left iliac fossa the sigmoid flexure of the colon, the ureter, and the spermatic vessels.

Although the upper boundaries of the abdomen are completely bounded internally by the diaphragm, they remain quite undefined externally. The diaphragm being a movable partition between the chest and abdomen, alternately ascending and descending in respiration, and by such changes have the effect of communicating a corresponding enlargement or diminution of one of these cavities at the expense of the other. Without attention to this fact, mistakes in diagnosis would be very frequent. A vessel, entering at the same point and in the same direction, may penetrate the thorax, or the abdomen, or both cavities, according to the position of the diaphragm at the moment of the injury.

The functions of the abdomen essentially require that its capacity should be continually varying; and had its cavity been circumscribed by an unyielding case, like that of the cranium, or by a construction like that of the parietes of the chest, such an arrangement would have been totally incompatible with the offices of the abdominal viscera. So circumscribed is Cruveilhier of the facility with which the plexus accommodates itself to the varying quantity of its contents, that he regards the doctrine as perfectly erroneous which relates the irreducible state of some hernia to insufficiency of space within the peritoneum.

ABDOMEN.

"What!" says he; "can we suppose a cavity incapable of receiving the bowels again, which will allow of eight or ten paroxysms of vomiting and drink being suddenly introduced into it? and which, as tympanites, often becomes distended in a short time to twice or thrice its natural dimensions?" According to the judgment of this distinguished pathologist, the obstacle to reduction depends either upon adhesions, or a disproportion between the viscera and the passage through which they protrude, arising from hypertrophy of the stricture or mesentery, or the altered relations of the peritoneum drawn down by the distended intestines. But, though this explanation, so far as it goes, seems correct with reference to the causes of the impossibility of reduction, Cruveilhier's view should not lead us to forget that certain cases every now and then present themselves where the viscera admit of reduction; but their return into the abdomen is followed by so much pain and indisposition, that the plan of keeping them there is unconditionally resigned.

In the treatment of several diseases and injuries of the abdomen, the surgeon cannot proceed one step with safety to his patient without the light of anatomy. Hernia, wounds, punctations, abscesses are all so many cases where a surgeon deficient in anatomical knowledge would be likely to adopt very inefficient measures, or commit the most fatal mistakes. A surgeon acquainted with the structure and extent of the sheath of the perineum would have no difficulty in selecting the most advantageous place for the puncture, when matter collects within that investment of the muscle, and the practitioner, aware of the exact course of the epigastric artery, would never run any risk of wounding it either in tapping a dropsical patient, attempting to take up the external iliac artery, or dressing the stricture in inguinal and crural hernia.

On being first consulted, surgeons, as well as physicians, too often neglect to institute a careful examination of the external parts of the body. Thus, either from carelessness or mistaken delicacy, they deprive themselves of the most simple, ready, and sure means of recognising the nature of the patient's complaint. Some diseases of the chest and abdomen are strikingly expressed on the surface; either in a permanent change of configuration, or in a temporary alteration of the normal movements, or both. (*Præcis, in Capite, of Pract. Med., art. Abdomen, Exploration of.*) When obstinate constipation, great pain, tenderness, and vomiting occur, let the surgeon always be sure that these symptoms are not dependent upon hernia, the usual situations of which should be carefully explored. The methods of exploring the abdominal regions are three, viz., inspection, manual examination, or palpation, as it is termed, and percussion. The assistance of the sight and touch alone is not what the practitioner should always be content with; for as there is more or

lives grow within the alimentary canal, and considerable arterial trunks perrade the abdomen, the sense of bearing may be exercised with as much success in the investigation of diseases of this part of the body, as in that of diseases of the chest. The parietes of the abdomen being capable of relaxation, the viscera may be felt directly through them; and, as Cruveilhier justly remarks, this is the only visceral cavity admitting of such exploration. Frequently, by means of palpation, tender, enlarged, or indurated points may be detected. In the first instance, however, a careful inspection of the surface of the abdomen should always be made. The practitioner should consider whether it is more bulky or of less size than natural. Swelling and tenderness, combined with pain, and a small, frequent pulse, characterize acute peritonitis. In some cases, a circumscribed swelling points out the seat of the disease—the organ affected. How essential the knowledge of the various regions of the abdomen, and of the contents of each of them, will here be for the formation of a correct opinion, need be sufficiently manifest. In pregnancy, retention of urine, and enlarged drupe, the swelling has an oval or protuberant form; in leucos, a broader, more expanded shape. In lead colic, the parietes of the abdomen seem retracted, or drawn inward. When palpation is instituted, the abdominal muscles should be relaxed, and the patient's mind diverted from his case. The pressure should be made gently and gradually; for when it is too forcible and abrupt, the examiner's touch is perjured, the patient is put to pain and his muscles contract. According to Cruveilhier, it has even been known to occasion the death of children by lacerating the liver, or the spleen in a state of enlargement. In fact, this rule made of palpation conveys to the surgeon no information which can be relied upon; for the tenderness, or pain experienced, or the change of countenance, may be more owing to the readiness or force of the pressure, than to any disease in the region of the abdomen subjected to examination. In certain cases, like ascites, the exploration should be made, if possible, while the patient is standing up, because in this position the fluid gravitates, and renders the parietes of the abdomen taut, so that the fluid is more plainly distinguished.

The presence of gas or liquids may be detected by percussion; that of liquids, or any foreign body, being made manifest by the dull, dead sound, and the perception of fluctuation by the hand applied to the point opposite that which receives the percussion.

In diseases and injuries of the abdomen, the diagnosis is often attended with considerable obscurity. It might be supposed, that as the soft and yielding parietes of this cavity facilitate the manual examination of its viscera, the detection of any painful point about them, and the slightest change of their shape or volume, nothing would be more easy than to trace disease in this part of the body through its different stages with great precision. But, as Cruveilhier remarks, this is far from being the fact. The vast number of organs contained in the abdomen, their great mobility, the frequency of their displacement, the multitude of their diseases, the tortuous character of their vitality, which sometimes less than attain a very serious state of disease, undisturbed by any violent pain; and, lastly, the difference of thickness of the parietes of the abdomen in different individuals, are undoubtedly the circum-

stances accounting for the frequent difficulty in the diagnosis. In surgical as well as in medical cases, the same uncertainty is experienced. Thus punctured wounds of the abdomen are treated on general principles, because the practitioner seldom knows exactly what viscera are injured. The same observation is applicable to contusions of the abdomen. A man who had a hemia received the kick of a mule on the belly; severe colic and vomiting ensued; several surgeons believed that these symptoms arose from the hemia being stimulated, and recommended an operation. Cruveilhier objected to this proposal, which, however, was carried into execution; the patient died, and on opening the body, the small intestine was found torn completely across. In the North London Hospital, a young man died this spring (1836) from the kick of a horse on the abdomen. During the four or five days which he lived after the accident, he frequently vomited, and the belly became considerably swollen. Effusion of blood or of the intestinal contents was feared; but until the post-mortem examination took place, the exact nature of the injury remained doubtful. A dissection of the small intestines was then directed, supplied with effusion of its contents. The result was peritoneal inflammation.

Dr. Serravallo, in his work on *Diseases of the Ovary*, relates the case of a young woman, who, after suffering better fever, the course of which was not unquiet, suddenly complained of some pain in the abdomen, and in a few hours expired. On opening the body, a large quantity of pus was found effused in the peritoneal cavity, in an abscess of the right ovary. Dr. Trevisan, with an ovarian abscess of the size of an orange, whose the prominent symptoms were uncontrollable vomiting and synchysis fever. (*Cases of Pract. Med.*, art. *Abscess*.) I have seen several instances of ovarian cysts which had become inflamed after tapping, and secreted a purulent fluid. A woman had an ovarian tumour supposed to be an ovarian drupe. After death the cyst was found to contain twenty parts of well-formed pus. (*North Amer. Med. Jour.*, 1836.)

In one case an abscess communicated with the coccyx, to which, and the parietes of the abdomen the osseum had become firmly adherent. In this manner a circumscriptum abscess was formed, containing ill-conditioned pus, and three or four seeds of fruit, covered by cartilaginous crusts. (*Abdomen on Dis. of the Abdom.*, &c., p. 284.)

Abscesses of the liver are more common in hot than temperate climates. Frequently the liver becomes adherent to the neighbouring parts, and then the matter may be discharged through the parietes of the abdomen, or into the colon, stomach, duodenum, or gall-bladder; from which latter the pus may descend by the biliary duct into the intestine, and be discharged per anum, an instance of which is recorded by Mayhew. Abscesses of the liver have been known to make their way through the diaphragm into the pleura, or into the air-cells of the lungs, so that the pus was coughed up. Atrial refers to one case, where an abscess of the liver communicated with the vena cava, and to another, where it burst into the pericardium. (*Anat. Pathol.*, t. ii., p. 601.) At the request of the late Dr. Pinckard, I examined the body of a woman, in whose liver there were nearly three parts of pus; the case was remarkable on account of the gall-bladder having been inflamed, with the exception of a

trical portion of its fundus, which is now in my possession.

The kidney may be the seat of acute or chronic abscess. Sometimes the quantity of matter is small, and the texture of the organ but little changed. In other examples, the suppuration may be so rapid that some of the cellular structure of the kidney is lost, excepting its capsular investment, which is expanded into a cyst of considerable size, and filled with pus. I attended with Mr. Baker, of Sturges, an old man, who had symptoms somewhat like those of stone, and one of whose kidneys was found, after death, converted into a cyst containing about a pint of purulent fluid. As Anstie observes, renal abscesses are sometimes so large that they may be felt through the parietes of the abdomen. (*Lancet*, 1860, p. 633.)

Abscesses of the kidney may burst in the loin, or sink their way into the peritoneum, the ureter, or the calyx.

Mr. Lawson, of Lexington, sent me the parietes of a tube where the pulsations of the aorta against a diseased liver, extending across the epigastrium, and occasioning a well-defined tumour at the pit of the stomach, had been mistaken for an aneurism of the aorta, which vessel was found perfectly sound after death.

I once visited with Mr. Miller, of Keppel-street, a thin old man for retention of urine, when the tumour, formed by distended bladder above the pubes, was attended with rigidity and strong pulsations, corresponding to those of the aorta.

I was attended with the late Mr. Estlin on a boy in Christy Hospital, who had a considerable abscess in the lumbar region, attended with distinct but feeble pulsations, corresponding to those of the aorta.

Three or four years ago I was also consulted by Mr. Gilchrist, of Ephraim, in a case where an enormous abscess in the epigastric region was accompanied by pulsations as strong and synchronous with those of the heart as the throbbings of an aortic aneurism.—C.]

[ABSCESS (from the Latin *abscessus*). A collection of purulent fluid in the texture or substance of any part of the body capable of suppuration. If the pus is not within the tissue, but merely poured out into some regular and natural cavity of the body, where it forms an accumulation, the case is said to be one of purulent effusion, or of suppuration in the particular cavity affected, whether lined by a mucous, a synovial, or a serous membrane. When, however, the purulent matter is inclosed by a various membrane, where it follows any surface, passage, or duct, from which it is promptly voided externally, without producing any accumulation, the patient is said to have a purulent discharge. Familiar examples of this are seen in gonorrhoea and purulent ophthalmia.

When purulent matter is confined, and not infiltrated through the structure of an organ, it constitutes an abscess, the boundary of which is formed either by the tissue of the organ itself, or by what is termed an accidental tissue. In both cases, the formation of the boundary is accomplished by the affinity of contiguous lymph, which in the former produces the mass and constitution of the tissues of the organ in immediate contact with the pus, and thus prevents its diffusion; in the latter it forms a more or less perfect membrane over the whole of the surface over which the purulent secretion has taken

place; and hence the pus being excluded, as in a shut ear, the abscess is sometimes said to be incapsulated.

The cysts of abscesses have the power of absorption. In this manner, the occasional expansion and retraction of its diaphragm, without either tearing or being opened, is accounted for. The cysts must evidently be also secreting surfaces; for, after the pus has been discharged, the cavity is soon filled with purulent fluid again.

Abscesses cannot be produced in certain textures. Thus, they cannot take place in the dense structure of fibrous or cartilaginous tissues, nor in that of serous membranes. When pus is discharged from these tissues, it is effused either upon their surface, or into the cavities which they invest, but abscess never forms in their proper substance. It is the prevailing doctrine, that abscess can take place only in parts into which cellular tissue enters as one of their constituents; and that this tissue is more frequently the seat of abscess than any other. John Hunter explained that abscess is more common in superficial than deep-seated cellular tissue.

For an account of the tendency of abscesses to make their way to the surface of the body, or into a passage lined by mucous membrane; the theory of suppuration; qualities of pus; the general symptoms and treatment of abscesses; and other topics relating to this interesting subject, see SUPPURATION.

It is a contested point whether an abscess can ever take place unpreceded by inflammation. Although John Hunter has a section in his work on the blood, entitled "Collection of Matter without inflammation," yet his doctrines are decidedly in favour of suppuration being an effect of inflammation. At the present day, I believe the best pathologists would mostly concur on this point with Hunter. Thus Dupuytren affirms that an abscess is never a primary disease, but invariably the effect or termination of a more or less intense and extensive inflammation of the living tissues. "Wherever," says he, "suppuration is observed in any part of our organization, whatever may be the qualities of the matter, we may be sure that some kind of irritation, acute or chronic, apparent or concealed, must have existed or must yet exist, either in the situation occupied by the purulent collection, or in some remote part which communicates with this point, and is the source from which the matter is derived." Dupuytren maintains that this proposition is founded on the most accurate pathological investigations, and admits of no exception, whatever may have been asserted respecting collections of pus, supposed to be the result of substances absorbed and circulated for a time in the vascular system. Whether abscesses form slowly or quickly, whether they attain a considerable size or remain within narrow limits; and whether they contain pus of one quality or another, inflammation of more or less intensity, according to circumstances, seems to Dupuytren, and I may say, to the greatest number of modern pathologists, to be always being concerned in their production. To this subject, however, I shall return in considering particularly the process of suppuration, under which head the formation, symptoms, and treatment of abscesses generally will be detailed. (See also ANTHRA, ANTHRA, ERYSIPELA, HYDROCELE, LUMBAR ABSCESS, MAMMARY ABSCESS, PARASTERNAL SCARF, and WHITLOW.—C.)

[ABSORPTION. The source of the lymph is

less certain than that of the chyle; for, even at the present day, M. Magendie, influenced by the possibility of injecting the lymphatics from the arteries, and by the uniform nature of the lymph, and in analogy to the blood, professes a belief, which was common many years ago, that it is not formed by the decomposition of the old particles of the body, nor by fluids absorbed from various surfaces, but that it is composed of the thinner parts of the blood, which, instead of returning by the veins to the heart, pass into the lymphatics, and are conveyed to that organ through the thoracic duct. The lacteals certainly have little disposition to take up anything but chyle; but, as Dr. Beudant has explained, "the lymphatics are capable of dissolving a great variety of substances, differing from each other most widely as their nature, so that it would almost appear as if, by a certain mode of application, any substance might be forced into them. Nor (says Dr. Beudant) is this conclusion affected by the hypothesis of M. Magendie; for, although we might agree with him in supposing that, in the ordinary operations of the system, the veins are the principal, or even the sole instruments in restoring the materials of which the body is composed, yet we have unequivocal evidence that, when certain poisonous or medicinal agents are applied to their extremities, they may be received or forced into them, and conveyed into the circulation. The case of metallic or other medicinal substances—that are taken up by the lymphatics, may appear to be less difficult to explain, because the absorption is generally produced by friction, or some mechanical process, which may be supposed to force the substance into the mouths of the vessels, or to produce an erosion of the epidermis, which may enable the substance to come into more immediate contact with the mouths of the vessels. We may also imagine that, when the component parts of the body are brought into close approximation with their capillary extremities, they are then taken up in the same way that the chyle is absorbed from the intestines." (*Elem. Syst. of Physiol.*, vol. ii. p. 363.) Many physiologists have little difficulty in conceiving how fluids can be taken up by the lymphatics, but rather stagger at the notion of this being also the case with the hardest solids. Others, however, accommodate their creed to both hypotheses, reconciling themselves to them by the argument that, if the minute capillary arteries can receive the densest matter, the small lymphatics can remove it. Our example is not more difficult to comprehend than the other. Yet such reasoning throws little light on the question, how are the solids prepared for absorption, and in what manner are they taken up? There, in fact, remains completely unexplained.

"What (inquires a pious physiologist) are we to conceive of the intimate nature of this operation? Is solution of the substance necessary, we are at a loss to find a proper solvent; many of the substances are insoluble in water, or in the serum fluid which is found in the vessels; while, on the other hand, it is perhaps not easy to conceive how the substance can be absorbed without being previously dissolved, and still more so how the solids can have their texture broken down, and enter the vessels, particle by particle, as it were, and be suspended in the lymph in a state of extreme comminution? These difficulties some physiologists, including Boerhaave, endeavour to diminish by arguing that the lymphatics

must be supposed to act only upon the elements of every texture, and that, on this principle, the absorption of solids is an exactly intelligible as that of fluids, the same elements frequently contributing to the composition of both.

While parts retain the vital principle, they resist the action of the absorbents. Dead matter is more easily acted upon by the absorbents than living; and, in fact, "no part can be absorbed until its texture is destroyed, and, consequently, until it is deprived of life. No substance can possibly enter the absorbents while a system is aggregated, so that it necessarily follows that the preliminary step to the absorption of the body is its decomposition." (*Beudant, Elem. Syst. of Physiol.*, vol. ii. p. 363.) This *disphysiologie* afterwards explains, that by the death of a part, according to absorption, is lost spiritual unity; that it is no longer under the influence of vital action. It therefore "loses its power to supply of matter which is essential to the support of all living parts, and the process of decomposition necessarily commences." A better account of the subject appears to be that which, dissolving all metaphysical and theoretical notions upon the supposed death and decomposition of parts previously to their absorption, represents the absorbents as acting directly upon the individual atoms, particles, or elements of the various textures. We know nothing about the vitality of these atoms or elements in their separate capacity; supposing them to possess it, we know nothing of the manner in which they depart with a previously to their entrance into the absorbent system, just as we are completely ignorant both of the manner in which such elementary materials acquire the vital principle, and of the exact moment when they *become* this or that.

It appears also, from various observations and experiments, that substances may enter directly into the bloodvessels, and thus get at once into the circulation, or else be conveyed from the surface on which they are placed, through a web the contiguous tissues, into the blood, by what M. Magendie terms *imbibition*. In both these modes, it is inferred that absorption does not necessarily require any action or substance of the lymphatic vessels themselves, the commencement of which, upon every surface and in every texture, by innumerable orifices or mouths, is not regarded by some distinguished physiologists at the present day as a doctrine by any means well established. Of course, what fluids would explain on this principle, they would refer to imbibition, in which the absorbed matter passes through the textures of parts into the circulation, or else gets more directly into the bloodvessels.—C.]

ANAUROSIS. Here the endemic application of strychnia deserves to be mentioned.

In the comments *unofficially* formed by experiment on light or *lightness*, we may clear out the alimentary canal with an active dose of calomel and jalap. Patients may then be exposed above the eyebrows; and if these fail, strychnia, or the external use of strychnia, may be tried. (*See Middlemore on Use of the Eye*, vol. ii.) In such cases Magendie would probably run on strychnia and continue over the frontal nerve.

In *anaurosis*, given the gradual effect of any exposure of the eye to real light, or of hard study by light of lamps or candles, the foregoing treatment would, I think, be less likely to answer. Here a slow inflammation of the retina has probably

been going on, followed by structural changes, the only chance of recovering which must depend upon depletion, mercury, and perfect rest of the organ. (See *Middlemore on Dis. of the Eye*, p. 325.)

In periodical amaurosis, attended with serious impairment or loss of vision, returning daily, weekly, or monthly, or at irregular intervals, the eye being little or not at all affected in the intermediate periods, the best means of cure are bleeding, purgatives, and counter-irritation. This treatment is especially applicable to hystericalgia.

In amaurosis excited by disease, the globe may be divided, mild laxatives and small doses of calomel or purgative given, and the child put into a warm bath. If amaurosis depend upon the irritation of a carious tooth, this should be extracted.

For amaurosis from a partial wound or laceration of the optic-nerve, the best plan is to make a free division of it.

Of late, strychnia has been employed as a remedy for amaurosis. It seems to Mr. Middlemore that its use should be confined to cases in which the nerve is in a state of atony from some direct action directly upon its texture, or upon its texture through the medium of the general debility of the system. At all events, he is of opinion that it should not be resorted to when there is much vascular fulness either of the system or the retina, or a tendency to inflammation. Its effects are likewise to be most carefully watched. An atonic state of the retina, or of some part of the nervous apparatus of the eye, productive of amaurosis, when unconnected with a full plethoric habit of body, determination of blood to the head, or any tendency to apoplexy, or any structural change either in the retina or its immediate nervous relations, may be treated by means of strychnia, particularly if tonic and general stimulants have been already unsuccessfully tried. The bowels are to be first freely opened, and spurious medicine occasionally given during the use of strychnia. Mr. Middlemore puts a narrow blister above the eyebrow of the affected eye, or above each eyebrow, if both eyes are involved; and after the crusts and scabs have been removed, sprinkles a small quantity of strychnia upon the raw surface, connecting with the fourth of a grain upon each side. If vision be not improved, this quantity may be gradually increased to two grains; the part is also dressed with styptic ointment. The strychnia is applied only once at twenty-four hours, and the eyebrow is protected as the place for its action, on account of the probable special effect of the strychnia upon the supra-orbital nerve, in addition to its other more general influence. If strychnia excite great local inflammation, it may be blended with a little flour or powdered opium. Mr. Middlemore observes, that, if the patient should become sensible of occasional flashes of light before the eye soon after the commencement of this treatment, there would be great encouragement to persevere; but that, if vision should be not at all influenced or improved after the strychnia had been tried a fortnight in sufficiently powerful but not independent quantities, it ought to be discontinued. Strychnia appears to him to be well adapted to the case of infants, whose eyes are affected with incomplete amaurosis, and who have been accustomed to follow their employment by means of a very feeble light, and also to cases of impaired sensibility of the mind, occasioned by too great a delay in curing

congenital cataract. (See *Middlemore on Dis. of the Eye*, vol. ii., p. 222.)

Strychnia has also been prescribed as an internal remedy for amaurosis.

The division into gouty and rheumatic amaurosis is more than doubtful.

"We can admit," says Mr. Lawrence, "that the nervous structure of the eye may be affected in the rheumatic and gouty, as well as in other persons; but it will require clearer evidence than we possess at present to show that there are distinct gouty and rheumatic amauroses." (*Lectures on Opth.*, p. 331.)—C.]

[AMPUTATION. Modification of a limb, after operation for aneurism, is another exception to the general rule of not amputating till the cicatrization has stopped. Where also gangrene arises from the obstruction of the circulation by an aneurism bursting, and its blood passing copiously into the cellular tissue of the limb, amputation should be performed without delay, though the cicatrization may not have stopped. An example of the success of this practice I have laid before the profession. (See *Med. Chir. Trans.*, vol. xii.)

DISEASED JOINTS.

Excluding from present consideration the proposal to splintate the extension of some joints which are in particular states of injury or disease, I may observe that *osteology joints*; with diseased bones and distorted ligaments and cartilages, is another case in which amputation may become absolutely necessary. As Mr. Pott remarks, there is one circumstance attending this condition often rendering it particularly unpleasant, which is, that the subjects are most frequently young children, so as to be incapable of determining for themselves, which inflicts a distressing task on their nearest relatives. All the efforts of physic and surgery often prove absolutely ineffectual, not only to cure, but even to retard the disease in question. Notwithstanding many cases admit of cure, numerous others do not. The disease often begins in the very utmost recesses of the cellular texture of the heads of the bones, forming the large articulations, such as the hip, knee, ankle, and elbow; the bones become diseased in a manner which will be explained in the article *Joints*, sometimes with great pain and symptomatic fever; sometimes with little or none, at least in the beginning. The cartilages covering the ends of these bones, and designed for the mobility of these joints, are totally destroyed; the epiphyses in young subjects are either partially or totally separated from the solid bones; the ligaments of the joints are so thickened and spoiled by the dissemper as to lose all internal appearance, and become quite unfit for all the purposes for which they were intended: the parts appointed for the secretion of the synovia become diseased in like manner. All these together furnish a large quantity of stinking serous matter, which is discharged either through artificial openings made for the purpose, or through small ulcers that open. These openings constantly lead to bones which are diseased through their whole texture. When the disease has got into this state, the constant pain, irritation, and discharge being so heinous symptoms of the most destructive kind, such as total loss of appetite, rest, and strength, profuse night-sweats, and so profuse purgings, which tell all the effects of weakness.

and bring the patient to the brink of destruction. (See *Pain on Amputation*.)

In these cases amputation is attended with more success when performed late than when undertaken at an early period, before the disease has made great advances. This is fortunate, as it affords time for a fair trial of such remedies as are best calculated to check the progress of the disorder. (See *Joints*.)

Whenever the disease of a joint is likely to terminate in ankylosis, amputation should not be resorted to, as a cure will be effected without it. (See *Ankylosis*.) In deciding to amputate or not, a great deal will depend upon the state of the patient's health and his kind of constitution, as well as upon the condition of the joint itself. Thus Dupuytren relates the particulars of two cases of distended elbow, with elevation of the cartilage, abscesses, sinuses, &c. In one, where the constitution was decidedly syphilitic, the hectic disturbance severe, the emaciation great, and the strength rapidly declining, the patient, a child, could only be saved by amputation. In the other case, where the constitution was less deranged and the strength better maintained, Dupuytren brought the disease to a conclusion by ankylosis. (See *Dupuytren, Clin. Chir.*, t. iv., p. 250.)

Surgeons should generally refuse to amputate limbs merely affected with stiffness or deformity. Operations under such circumstances, termed by the French *opérations de complaisance*, are more frequently followed by fatal consequences than amputations in more urgent cases. (See *Dupuytren, Clin. Chir.*, t. iv., p. 271.)

The ease with which the flow of blood through the largest arteries is commanded by manual pressure, is a fact attested by Dupuytren, who only employed the instrument which he terms the compresser in a few special cases. (See *Lepois Order, &c.*, t. iv., p. 377; *Elements*, part iii., p. 361; and *Ed. Med. and Surg. Journ.*, vol. xx., p. 241.) The following passage explains Mr. Liston's views of this subject: "In all cases, and in all situations and circumstances, hæmorrhage can be restrained during the completion of the incision, and during the employment of means to close the cut ends of the vessels, by means of very slight but exact pressure on the trunk of the principal vessel. (See also *Dupuytren, Lepois Order de Chirurgie Chir.*, t. iv., p. 382.) The point at which this should be applied should be at as short a distance as possible above the site of the incision, and, at the same time, above the origin of any branches which must be cut. Not the slightest pressure should be made until the instant when the incisions are about to be completed, so that no venous congestion may take place in the limb. All the blood in the limb below the incision must necessarily be lost. The veins are once really congested, then the arteries, and pressure made a short time before the operation may arrest the return of blood, while it may not stop its reflux. Thus, engagement of the lower part of the limb is produced, and the quantity of blood that must be lost is increased. For a similar reason, pressure sufficiently firm to stop arterial hæmorrhage is to be continued till the principal branches are tied, and then entirely removed, for the continuance of even such pressure will increase the flow of blood from the surface of the stump—blood flowing in, and being arrested in its venous return, trickles out through the open ends of the vein. If a circular band be used for the compression, such as the

screw-tourniquet, it should be put on quickly, screwed tight once, and then the tourniquet should not be delivered one instant." The doctrine and practice of Baron Dupuytren I will notice in the article HÆMORRHAGE. Baron Dupuytren did not employ the common tourniquet, nor any kind of compress furnished with a handle (see *Lepois Order de Chirurgie Chir.*, t. iv., p. 285); he sometimes avoided himself of an instrument which he termed a *compresser*, and which makes pressure only on two opposite points of the limb. (See *Lepois Order, &c.*, t. iv., p. 346.)

VARIOUS BAD CONSEQUENCES MAY FOLLOW AM- PUTATION.

As, for instance, rupture of the stomach, hæmorrhage, severe inflammation of the crura, abscesses and extensive sinuses, inflammation of the medullary membrane, necrosis (see *B. Phil. Mag.*, in *Lond. Med. Gaz.*, for 1833, 34, p. 189; protrusion of the bone, phlebitis, and suppuration in internal organs and in various other parts of the body, hospital pyæmia, &c. Of these several complications, which may either interrupt organization, or subject the patient to great and protracted suffering, it even lead to a total termination, some are common to every operation, others restricted to that which is now under consideration; some arise from external causes, others from internal. (See *Dupuytren, Lepois Order, t. iv.*, p. 425.) It is only necessary to refer to a part of these topics in the present place, because the others more properly belong to the articles HÆMORRHAGE, GANGRENE, NECROSIS, PHLEBITIS, SUPPURA, PYÆMIA, and TETANUS.

OF NEUROMATA AFTER AMPUTATION.

Sometimes amputation has been found necessary a second time, in consequence of a morbid protuberance of the nerves of the stump—a change noticed by Molinæ, Morgagni, Lower, Anstomus, and Prochaska, and always attended with excruciating pain and great instability of the part, and sometimes with retraction of the skin and protrusion of the bone. According to Mr. Liston, neuromata are most frequent after amputation of the arm and forearm than after amputations. The disease seems to him, however, to be less common than formerly, which he ascribes partly to discompositions having been more extensively adopted, and partly to the method of tying arteries, so as to include nothing else in the ligation. In the forearm I have seen only a neuroma follow amputation, and not above all the operations were curable. Sir Astley Cooper, in his Lectures, relates one instance of such a thing high up the arm, where, upon amputation of the part near the girth, a tumour was felt, which, when touched, made the patient jump as if he had been electrified. In the case, as the bone protruded, superstition at the shoulder was performed. In another example, where a ligature was in a painful, irritable state from a similar cause, Sir Astley Cooper effectually relieved the patient by removing the diseased end of the posterior spinal nerve. This plan should always be preferred to amputation, when it presents any chance of being efficient. In a third instance, amputation was repeated at the patient's desire, and the nerves were found enlarged, forming a ganglion which partly rested upon the extremity of the bone. Still a degree of irritation had been produced by it, that no part of the stump could be touched without exciting a kind of dis-

trip shock. In a case that occurred in the Middlesex Hospital, amputation of the thigh was performed a second time, in consequence of the first stump being thus diseased. A complete plegia, or plexus of nerves, was found closely adhering to the removed portion of bone, having assumed the appearance of cartilage. The os femoris was of an unusually small size, but the linea aspera larger than natural. (See *Lancet*, vol. i, p. 115; vol. vi, p. 192.) In the same hospital, Mr. Mayo also amputated at the hip, on account of the extreme suffering caused by a diseased state of the nerves of a thigh stump. (See *News*.) For such observations on the changes which occur in stumps after amputation, see STUMPS.

ON THE OBLIQUE OR OVAL AMPUTATION OF THE LEG.

The method adopted by M. Sedillot consists in dividing the integuments on the outer side of the leg obliquely, from before backward, and from below upward. The aneurism then carried round the posterior part of the limb to its inner side from behind forward, and from above downward. The division of the integuments is next completed in front by a transverse incision, leaving an oval wound, with its anterior angle truncated.

The only difference in the process of M. Blandin from that of M. Sedillot consists in making the incision through the skin entirely oval, and leaving the knife directed about an inch lower down in front than behind.

"One reason," says M. Malgaigne, "not mentioned by my writer, makes me prefer the oval even to the circular method. In the latter, the principle is to leave the integuments sufficiently long on every side to cover one half of the stump. Now the posterior integuments, on the retraction of the muscles, reach the centre of the wound more readily than the integuments in front, which have to pass and bend over the end of the tibia. The object then can only be fulfilled by allowing a greater length to the skin in front."—(*Manuel de Méd. Opér.*, p. 293.)

Oval amputation of the leg seems to me the most tedious and painful of all the modes hitherto proposed of removing this part of the limb. Nor can it be necessary, if care be taken in the other methods to save a sufficiency of the integuments in front of the limb, as advised in the descriptions already given of those operations.

AMPUTATION AT THE ELBOW-JOINT.

Depuytren, convinced of the correctness of the principle that as much as possible of the upper extremity should always be saved, termed the practice of amputating at the elbow whenever the state of this part and of the soft parts admitted of such operation. The humerus being slightly bent, a double-edged knife is introduced transversely in front of the joint from one condyle to the other, and a flap made of the soft parts of the upper and anterior part of the forearm. The day is now selected, the axillary and lateral ligaments cut, and the operation finished by the surgeon making through the sheath from before backward. The brachial artery is not divided, cut the radial and ulnar. The bleeding vessels having been secured, the flap is brought over the end of the humerus, and secured in this position with long strips of adhesive plaster.

When there is not a sufficiency of soft parts left for an integument flap, Depuytren used to amputate at the elbow with the circular method, the first incision through the skin and fascia being

begin three finger-breadths below the condyles. The integuments and fascia were then drawn upward, the knife applied just below the edge, and the muscles divided down to the bone. By next carrying the knife a little upward, and separating the soft parts from the bone, the joint was reached, and opened by cutting the lateral ligaments and forepart of the capsule. The operation was completed by dividing the sheath with the saw. (See *Depuytren, Leçons Orales de Clinique Chir.*, t. iv, p. 308.) Amputation at the elbow was practised by Depuytren in ten or twelve examples with great success, and the method is highly recommended by Mr. Liston. (See *Elem. of Surgery*, part iii, p. 281.)

[Dr. John Kearney Rodgers, of New-York, has twice amputated at the elbow, once after the method of Depuytren, and once removing the sheath during the operation.—*Revue*.]

AMPUTATION AT THE WRIST, OR RADIO-CARPAL ARTICULATION.

The hand may be amputated at the joint of the wrist whenever the disease does not extend too high, and a flap can be made either from the integuments of the back of the hand or from those of the palm. Liston makes both an anterior and a posterior flap. The circumstances of the case should determine the choice. Here amputation may also be done by the circular incision. The scaphoid, sesamoid, and carpal bones form a convexity which is almost entirely received in the concavity of the radius, the ulna having no connection with this joint except through the intervention of the triangular ligament, and to the extent of about four lines. The styloid processes of the radius and ulna can be readily felt, and below them the articulation continues; but, as Malgaigne observes, the direction of the joint is less easily determined; and if, while the hand is extended, the wrist itself be alternately bent and extended, these motions will take place in the radio-carpal articulation, into which the surgeon might erroneously carry the knife. The following are the instructions given by M. Malgaigne for the avoidance of this mistake:

1. If the hand be extended very much backward, the spot of the angle formed with the forearm will denote the radio-carpal articulation.
2. The transverse projection of the radius forward may also be felt, the joint being one line below it, and about five lines above the continuous wrinkle between the palm and the forearm.
3. The situation of the ends of the styloid processes being determined, and a line drawn across from one to the other, the middle of the joint will be two lines and a half above such transverse lines.
4. If only the styloid process of the radius is perceptible, that of the ulna is known not to descend so far as a by two lines; and the middle of the joint is three or four lines higher.—(*J. P. Malgaigne, Manuel de Méd. Opér.*, p. 394.)

The projection of the radius and carpal bones beyond the level of the palmar surface of the radius and ulna must be remembered in the operation.

Amputation by the circular method is performed as follows: An assistant draws up the integuments, and the surgeon makes an incision through them all round the wrist, about an inch below the styloid processes. The skin may now be easily retracted nearly as high as the joint; a severe incision, made so as to leave the palm

and sometimes bones just beyond it, divides all the tendons on a level with the retracted skin. The joint is then to be cut into on one side or the other, under the guidance of the corresponding stylized process, and the knife directed through the articulation in a line answering to the posterior-superiority of the acromion, humeri, and coraciform bones. The radial and ulnar arteries are now to be tied, but the interosseous have seldom requires a ligation. The wound is to be closed with the line of it in the transverse direction, and the stump placed in a depending position, so that, if suppuration take place in the tendons or vessels or under the bone, the matter may not pass far up the limb.

In the double *hyperamputation*, as executed by Lisfranc, the hand and forearm are placed in the supine position, and supported by an assistant, who at the same time makes pressure on the radial and ulnar arteries. The surgeon, with a narrow knife, transfixes the soft parts on a level with the styloid processes, and from the radius towards the ulna, or from the ulna towards the radius, according as he is operating on the right or on the left limb. The knife is then carried along the anterior surface of the corpus, and its edge inclined forward so as to make a semicircular flap about two inches in length. This flap being held back, another very similar one is made on the back of the wrist; the extrinsic tendons are then to be cut through easily on a level with the articulation, the joint opened just below one of the styloid processes, and the disarticulation finished as in the circular method.

When the soft parts are so diseased that two flaps cannot be saved, the operation may be done with a single one, which should then be made somewhat longer.

In several cases of injury from the bruising of firearms, by reason of the laceration of interosseous on the palmar surface of the wrist, it has been found impracticable to have lost one flap, and that brought from the back of the wrist. In these cases of amputation at the joint, I have not met with any impediment in making a good stump. There can be little doubt that it is preferable in all cases to amputate at the wrist for injuries of the hand, instead of operating midway upon the forearm or above the wrist, as some surgeons have been in the habit of doing. Not only is there less trouble in healing the stump over the end of the radius than over the ends of two bones, but fewer ligatures are required, seldom more than two; and, what is still more important, the patient will find the stump more useful to him in after life.—*REMARK.*

AMPUTATION AT THE HUMERUS.

The propriety of the operation in *hyperamputation* is now perfectly established.

Thus, as M. Velpeau observes, a comminuted fracture, an *os-seo-carcinoma*, a *spina-ventosa*, any incurable disease of the bone extending above its shaft; gangrene; in short, any disease reaching to the vicinity of the hip, and so serious as to require the removal of the limb, are cases for amputation at this joint, provided the acetabulum and the bones of the pelvis be unaffected. It is indispensable for gunshot wounds of the upper third of the thigh, combined with fracture. (See *Nouv. Éléms. de Méd. Opér.*, t. i., p. 510.) It was performed by Mr. Mayo for a neurilic affection of a thigh stump.

AMPUTATION AT THE SHOULDER-JOINT.

The head of the humerus represents nearly

the half of a sphere, scarcely one third of which is recovered by the glenoid cavity of the scapula, the rest being contained in the extremely loose capsule of this articulation. The intrinsic muscles are held together principally by the *deltoidei*, *supra-spinatus* and *infra-spinatus*, *teres major*, and *sub-scapularis* muscles. The joint is also very much strengthened by the tendons of the long head of the biceps, and by the necessary ligament extending from the acromion to the upper part of the humerus. Above the articulation is a kind of osseous-fibrous cap, formed by the acromion, the coracoid process, and the ligament stretched between them. The arch projects more than an inch in front of the glenoid cavity, and descends farther in the direction backward than in that forward. (See *J. F. Malgaigne, Manuel de Méd. Opér.*, p. 328.) If we examine the anatomy of the shoulder from above downward, we first meet with the *deltoidei* muscle, covered by the *effluviament*, *over* three of the pterygia, and a very thin skin. Then we come to a loose cellular tissue, the tendon of the *supra-spinatus*, *infra-spinatus*, *sub-scapularis*, and *teres minor*, the necessary ligament and fibrous capsule, and the tendon of the long head of the biceps. Lower down we arrive at the scapular portion of the triceps, and then the fascial plexus of nerves, the arterial vessels; and, under the skin, the *pectoralis major*, the *lanceolatus dorsi*, and the *teres major*.

The apex of the acromion is very perceptible just above the cushion of the shoulder, as well as the coracoid process more towards the chest. Between these bony points is situated a triangular interval, useful to be recollected by the practical surgeon, bounded outward and downward by the head of the humerus; above by the *clavicula* and *acromion*, or, rather, by the *os-seo-epitrochiale* ligament; and inwardly by the *coracoid process* itself. This is the place where the joint may be at once cut into without any incision from the bones; and it is on the knowledge of this fact that Lisfranc proposed one of his methods of amputating at the shoulder. When the posterior border of the coracoid is reflected towards the scapula, as Velpeau observed, the knife may be made to pass below the acromion into the superior and external part of the joint. In some persons, the acromion is much more prominent than in others; and occasionally it is considerably depressed, so that its humeral aspect forms a deep concavity. In children it is cartilaginous; and Velpeau found it in two adult bodies separable by a very slight effort, as an epiphysis from the spine of the scapula. (Velpeau, *Nouv. Méth.*, t. i., p. 428.) The course of the circumflex arteries, that of the circumflex nerve; the situation of the necessary space extended from the acromion to the humerus; and, in particular, the origin and track of the tendon of the long head of the biceps, between the fibrous capsule and the synovial membrane into the humeral groove of the humerus; the insertion which the *myositis* is attached to the humerus just below its anatomical neck; the very specific form formed by the junction of the head with the shaft of the bone; and the circular shape of its head, requiring an incision of corresponding figure for the prompt division of the fibrous capsule, are all interesting points of surgical anatomy, without a due knowledge of which a surgeon cannot amputate at the shoulder with skill and judgment.

The principal methods of amputating at the

shoulder are comprised under four varieties: 1st, the operation with one flap; 2d, with two flaps; 3d, by the oval method (Scarsdale); 4th, by a circular incision (Alcock, Scarus, &c.). Here one fact needs particular attention, namely, that no mode of amputating at the shoulder can be exclusively justified in all the cases requiring the operation, because the soft parts around the joint are frequently destroyed, or very much injured in a greater or lesser extent, so that the surgeon is obliged to save skin and muscles whenever he can find them. On this point, Desautel fully agrees with the surgeons of the British army.

AMPUTATION OF THE FINGERS AND OTHER PARTS OF THE HAND.

Amputation of the fingers, or parts of them, is performed with one or with two flaps, with a circular or an oval incision, and frequently required, either primarily or secondarily, on account of various accidents and diseases, as comminuted fracture, dyschiria maligna, necrosis, &c. The best surgeons all agree with Mr. Searcy, that in general the operation is most conveniently performed in their articulations, though exceptions sometimes occur in which it may be done elsewhere, and the phalanx divided with the cutting-pliers. Thus it occasionally happens that either the distal or the middle phalanx is torn off, and the end of the proximate phalanx exposed; here, instead of removing the whole of the middle or of the proximate phalanx (as the case may be), it will often suffice to take away the diseased portion of it with the cutting-pliers, and save a proper flap for covering the end of the remaining part. As Mr. Liston has explained, it is sometimes desirable to save as much as possible of the proximal phalanx when amputation is rendered necessary by illness of the middle articulation, or of the distal extremity of the bone. In such cases two semicircular flaps are made by cutting from without, either on the lateral, or on the palmar and dorsal aspects, and the bone is divided either with a small saw or the cutting-pliers. (Elements, &c., part iii, p. 324.) When an injury just includes the joint and no more, Mr. Guthrie desires it better to saw through the bone than to operate at the next articulation! (On Gunshot Wounds, p. 384.)

AMPUTATION OF THE DISTAL AND MIDDLE PHALANXES.

The distal bones are but loosely supported by the anterior ligament, and behind by the extensor tendons: at the sides, however, they are much more closely held together by the lateral ligaments. Consequently, it is those which must be divided in order to lay open the joint freely. The line of the articular interval is nearly transverse. Between the distal and middle phalanx it is on a level with the palmar cutaneous furrow; but in the articulation of the middle with the proximate phalanx, it is a line and a half below the palmar furrow. (See J. B. Malgaigne, *Manuel*, &c., p. 205.) In either of these joints the operation is done in a very similar manner; either with a single flap, taken from the palmar surface of the finger, and long enough to cover the whole surface of the wound, or with two flaps, the longer one being turned on the palmar side, and the shorter one on the back of the finger. The surgeon, taking hold of the finger and placing it in the bent position, makes, with a narrow latissimus, an incision (I should say a semicircular one) across

the prominence of the articulation, or, as Malgaigne directs, half a line below it. Thus the skin is divided, and the posterior part of the capsule generally opened with the same stroke. If it be not, the surgeon, without stopping to effect this, may proceed to cut the lateral ligaments one after the other; and the two being next converged through the articulation, the operation is completed by the insertion of the palmar flap, which is to be the larger of the two, and long enough to cover the greater part of the wound. (See Desautel, *Leçons Orales de Chirurgie Clair.*, t. iv, p. 205; Malgaigne, *Manuel*, &c., p. 206.) When both phalanges are to be removed, the dorsal incision should end on each side precisely on a level with the terminations of the cutaneous palmar furrow.

Another method, ascribed to Lisfranc, consists in attacking the joint on its palmar side. All the fingers are bent except that which is about to be amputated. The point of a narrow straight bistoury, with the edge directed towards the extremity of the finger, is introduced half a line beyond the palmar cutaneous wrinkle if we are amputating the distal phalanx, and exactly at the base of this wrinkle if we are removing the middle phalanx. The knife is to pass through the finger from one side to the other, and close to the lateral and anterior surfaces of the bone, along which it should be carried to the extent of six lines, and then brought out so as to complete a semicircular flap. The knife is then carried again to the base of the flap, to divide the anterior ligament. In this operation the lateral ligaments scarcely require to be cut separately; for the same stroke of the knife by which the anterior ligament is cut, necessarily cuts them also, and makes room for the knife to be recovered through the articulation. Lastly, the tendons on the dorsal aspect are divided, without any posterior flap being made. By this method a more regular and better-nourished flap is produced, and the operation is more sure of being effected with precision; but the extensor tendon is apt to remain too long, in which event its projecting end should be cut off with scissors.

The circular method of amputating a finger is the oldest. The finger is put in the extended posture; a circular incision is made three or four lines beyond the articular interspace, the situation of which is denoted by the position of the palmar cutaneous furrow. The skin is dissected up as far as necessary, and the joint opened either in front or behind, as in the flap-operation already described. Or, if the disease or injury will admit of it, the integuments may be drawn up before the circular cut is made, and thus little or no dissection of them from the adjacent parts will be necessary. In general, after amputation of the distal and middle phalanges, the bleeding ceases as soon as the wound is brought together with adhesive plaster, and no ligature is required.

AMPUTATION AT THE METACARPAL-PHALANXIAN ARTICULATION.

Each of these joints is of the enarthrosis kind, and furnished only with loose ligaments. What is termed the knuckle, or the articular prominence, seen when the phalanx is bent, is formed by the head of the metacarpal bone. The joint is commonly about ten or twelve lines above the digital commissure.

1st Method.—The hand being placed in the pronated position, and the other fingers held apart

from the one about to be removed, the phalanx is to be bent, as Liston specifies, to an angle of 45°, and an incision begun over the head of the metacarpal bone, about three lines beyond the articulation, and extended obliquely down to the side of the finger, on a level with the distal epiphysis, care being taken to divide as completely as possible the extensor tendon. The incision is then carried to the palmar aspect of the joint, and the first flap completed, which is to be reflected. The knife is now pushed into the exposed side of the articulation, the ligament cut, and the operation finished by the formation of the opposite flap, which ends, like the first, at the distal condyloid.

The following is Mr. Liston's description of this method: The operator seats himself before the patient, grasps the finger so as to manage its movements with the left hand, and, holding the knife perpendicularly, with its point upward, lays it over the knuckle, and carries it obliquely upward, so as to open that side of the amputation. He then pushes the finger towards the opposite side, and with the point of the knife completes the loosening of the articulation, which should never be done with the blade, as it would cross-cut and mangle the skin. After the separation of the base of the phalanx with the point, the blade is passed behind; and, being carried downward and outward, it forms a flap similar to the first. They are retained in contact by bringing the neighbouring fingers towards one another. In general, this will also stop the bleeding, but sometimes one or both digital arteries will require ligature. (See *Liston's Elements*, part III, p. 373.)

When this operation is done on the index finger, the outer flap should be the larger; when on the little finger, the inner flap should have the greater size. (See *J. F. Malpouge, Manuel*, &c., p. 310.) Depuytren, instead of cutting the integuments obliquely, preferred dividing them perpendicularly, and making a semicircular incision, directed from the dorsal towards the palmar aspect of the finger. Another semicircular flap was next formed on the opposite side. As Depuytren found that, when the ring or middle finger had been removed, without taking away the head of the corresponding metacarpal bone, the adjoining fingers remained widely separated at their base, but obliquely approximated to one another at their extremities, so as to produce a considerable deformity, and an impeded action in their function, he used not to be content with amputating the phalanx, but made it a rule to apply a retractor, and saw off the head of the metacarpal bone. (See *Liston's Elements*, &c., t. IV., p. 369.) I know that Sir Astley Cooper has long advocated the same practice, which is most readily accomplished with a pair of strong cutting-pliers. The extension of this to one of the metacarpophalangeal articulations may also be another reason for taking away more or less of the metacarpal bone along with the finger. If merely the distal end of the bone is affected, the following plan of operation will suffice; but, as is remarked by Mr. Liston, if a considerable portion of the metacarpal bone is to be taken away, the palm should be left unimpaired. "With this view, the knife is extended over the dorsal centre of the bone, above the diseased part, and carried straight downwards till near the articulation, when it is made to diverge for the formation of lateral flaps. The incisions in the track of the wound are then directed backward, so as to expose the

bone completely, and the history is passed round it throughout its whole extent, the edge being kept close to it. Then the bone is clipped at the proper joint by the cutting-pliers; or the section of the bone may be performed before the separation of the soft parts from its outer surface, as by raising the cut end this part of the operation may be facilitated." (See *Liston's Elements*, part III., p. 377.)

AMPUTATION OF THE THUMB.

If merely the anterior extremity of the metacarpal bone were diseased, the bone might be divided with the cutting pliers, as is to remove the part affected, amputation being done either with the circular incision or a flap. (See *Vulpes, Nouv. Éléms. de Médec. Opér.*, t. I., p. 389.) An operation more frequently practised, however, is disarticulation at the joint, between the metacarpal bone of the thumb and the trapezium. The metacarpal bone is almost subcutaneous at its posterior and external aspect, but covered by a thick mass of muscle on the side towards the palm. The direction of the articulation is oblique, corresponding to a line, which, if carried far enough, would cross the root of the little finger. It has a loose capsule, and may be opened with the greatest facility at its two posterior thirds. The tendons of the long abductor and short extensor lie over the superficial side of it. The radial artery runs over its ulnar side in its way to the palm, to form the deep palmar arch. The tendon of the long extensor lies behind, and that of the long flexor in front of it. The plane of the joint is readily determined by passing the forefinger over the dorsal aspect, or the side of it, from before backward, for it is situated immediately behind the first bony tubercle. (See *Vulpes, Op. cit.*, p. 390.)

Let Method.—While the thumb is still in the position of abduction, the knife is applied to the middle of the commissure; an incision is made at once down to the carpus, the edge being carried close to the ulnar side of the metacarpal bone, which is about to be taken away; the joint is then opened by cutting outward, the flexor tendons divided rather with the point than the blade, so as not to grope out the skin; the thumb abducted and dislocated, and a flap formed from behind forward, by carrying the knife close to the outer side of the bone, and a few lines beyond the metacarpophalangeal joint. If the radial artery itself has been wounded, it must have a ligature; but, in other cases, turning the flap accurately over the wound will stop the bleeding. Besides splitting adhesive planes, the flexor, and especially its base, should be exposed with a compress and bandage.

2d Method.—An assistant takes hold of the thumb, while the surgeon takes as much of the soft parts as possible with the fingers of his left hand, and draws them outward. The latter then transfixes them with a straight narrow knife from behind forward or towards the palm, drawing the blade close to the radial side of the articulation. A flap is then formed; and, while this is held up by the assistant, the surgeon takes hold of the thumb, cuts through the joint from without inward, laxates the bone, and with the knife cuts through the middle of the commissure. This method leads to the same result as the former, but, being more difficult, would not be preferred.

3d Method.—Vulpes has frequently amputated the thumb in the following manner: An incision

is made along the back of the thumb from the styloid process of the radius to the commissure of the thumb and forefinger. This divides the integuments, the tendon of the long extensor, and a portion of the first interosseous muscle, so as to expose the joint. While an assistant holds gently the edges of the wound, the surgeon opens the capsule and dislocates the bone, which is then removed, care being taken to preserve as much of the flesh on the palmar side as will be required to close the wound immediately. Thus the palm of the hand is not at all wounded.

40, or *Distal Method*.—The operation is begun as in the foregoing plan. The knife is carried round the anterior aspect of the root of the thumb, and then over the dorsal one, thus severing all joining the extremity of the first. The point of the knife is next introduced into the articulation, which is cut through from its distal towards its palmar boundary. All that now remains to be done is to detach the bone from any fibres which may yet adhere to it, by carrying the knife in front of it from behind forward. The wound, when brought together, represents a straight line. (See *Figures*, *Pl. xiv.*, p. 392.) This method was described by Lisgar, Beckard, &c.

In hip-amputations of the leg, if appears to me that the anterior flap of integuments should be made longer, and the posterior flap of the integuments and muscles of the calf about one third shorter than is generally done. By this means the front of the legs will be better covered, and the frequency of excoriation diminished, while there will also be the advantage of the surface of the wound being considerably lowered below, where matter is disposed to form and lodge.

In the United States, amputation or excision of the clavicle was performed for the first time by Dr. Mott in 1828. In the twenty-first volume of the *Med. Chir. Trans.* are the particulars of a similar operation executed by Mr. Travers. Other cases I have noticed in the article *Bones, excision of*. In Mr. Travers's case, the operation was performed on account of a tumour of the clavicle. "A crucial incision was made through the integument and platysma myoides, one limb of which was nearly in the line of the clavicle, and the other at right angles, and the flaps and fascial coverings successively dissected down to the external base of the tumour. The pectoralis and deltoid muscles were then carefully detached from their clavicular origin, avoiding the costal nerve, and the fibres of the trapezius and cleido-mastoid muscles displaced on a director. One considerable vessel, in the situation of the transversalis humor, required a secure ligature. The circumference of the tumour was now well defined, though it as broad to be firmly imbedded, and sufficient its posterior aspect. Disarticulation of the apical extremity of the bone was next effected about difficultly, and the mobility thus communicated to the mass facilitated the completion of the operation. A director was now worked beneath the bone, as near to the sternal articulation as was practicable, and with a pair of strong bone nippers thus introduced, it was completely and cleanly divided. The subclavian muscle and a part of the rhomboid ligament were now detached from the tumour, and the mass being well raised by an assistant, while the edges of the wound were kept wide apart, by metallic retractors, the cervical psoealgia

of the tumour were separated from their remaining connections by a few touches of the scalpel, without injury to the subclavian vessels." The loss of blood did not exceed twelve ounces. The case terminated so favorably that there was scarcely any falling forward of the shoulder, nor any restriction of the motions of the arm. The young gentleman elevates it perpendicularly over his head, extends it horizontally, dines and sits at it behind the trunk, and performs the same extent and variety of circumference, and with equal promptitude and power, as the parallel movements of the opposite arm. The production of bone from the truncated sternal extremity of the clavicle extends at least two inches, and terminates beneath the centre of the cicatrix in a firm ligamentous band, adherent to the skin. (See *Med. Chir. Trans.*, vol. xxi., p. 138, &c. p. C.)

(In the *Amer. Jour. of the Med. Sciences*, vol. xxi. and xxiv., Nos. 44 and 51, p. 336 and 135, Dr. Geo. W. Norris, of Philadelphia, has published two papers, entitled "Statistics of Amputation," drawn from the records of the Pennsylvania Hospital. They have been prepared with great discrimination and skill, and in point of practical importance possess great merit, as exhibiting the results of this operation in the greatest variety of cases. They are highly creditable to their author for their originality, this being the first report of the kind ever published. Thus they are appreciated by the profession at home and abroad; shown in the fact that, since their publication, similar reports have been published by the Massachusetts, Liverpool, and University College Hospitals, and also by the Edinburgh Infirmary. The greatest benefits must result from these statistical publications in this and other departments of the profession, furnishing as they do the precise kind of information surgeons know how to estimate. The advantages of the numerical method in the collation of medical facts are becoming more and more obvious in every department.

That about one fourth of the patients subjected to amputation fail to recover, is the point which the statistical tables both of Dr. Norris, and Dr. Hayward of Boston, seem to establish; and hence our success in amputation would seem to better than that of European surgeons. That this may be true of hospital practice is possibly the fact; but to affirm that a similar proportion of fatal cases occur after this operation in private practice, is to do justice neither to American surgery. Professor Paul F. Eys, of Georgia, has denied the correctness of the inference sought from the foregoing statistics, and has published an article on the subject in the *Southern Medical and Surgical Journal*, and another in the *Philadelphia Medical Examiner*; and he appeals to the experience of Professor Mott and Professor Gibson in proof that deaths after amputation in private practice are very rare. Dr. Eys has himself amputated thirty-four times without losing a single case, and hence it was natural for him to reiterate against the representation that one fourth of the patients die after amputation.

The venerable Dr. John C. Warren, of Boston, informs me that he has performed eighteen amputations of limbs in private practice, of which seventeen were successful. But the same operation in hospital practice has been much less prosperous in his hands, for out of forty cases, ten died after amputation. I have no particulars

in relation to the nature of the sepsis which were fatal, although there are reasons which render any original operation in hospitals less successful than in private practice. The depressed constitution and intemperate habits of the great majority of hospital patients are, perhaps, among the most frequent causes of unfavorable results, as well as the late period of the diseases or injuries requiring amputation at which even such patients will consent to go to the hospital or submit to the knife.

In the late number of the *Boston Medical and Surgical Journal*, April 16th, 1861, an interesting case is reported, in which amputation was performed for a tubercular disease of the elbow-joint, which had resisted Lugol's iodine, iodoform and all other medications, in the Massachusetts General Hospital. The operation was performed by the elder Dr. Warren.

Dr. Allen Goldsmith has had extensive experience in amputation, and has never lost a patient when the operation has been performed for disease. Amputation after accidents, injuries, fractures, burns, and the like, have been in his hands most generally fatal, which he ascribes to the shock the system has suffered in such cases. He thinks his uniform success in amputating for the removal of disease is owing to his diligence in supporting the system by quinine, wine, sea-bathing, and other cordials, instead of depleting and reducing the patient, as is often done.

Dr. Moit, of New-York, has amputated at the hip-joint and shoulder-joint successfully. In amputations of the thigh, he prefers, after much experience, to transect the limb, and make the double flap above and below. He has found primary amputations decidedly less successful than secondary, and, with a view to the result, always prefers the latter. In the occurrence of traumatic mortification, he amputates before this process is stopped, if the state of the general system will at all admit of it. So, also, in the mortification consequent upon tying a large artery for aneurism in the extremities, he advises a similar course.

In spontaneous mortification, or gangrene, arthritis, Dr. Moit has amputated four times when the mortification was spreading, the earlier period having been lost; once on the thigh, and three times on the leg. Two thigh cases and one of the leg recovered.

Secondary hemorrhage after amputation has been generally arrested by list and pressure, with list upon the stump. In one case he found it necessary to tie the femoral artery in the middle of the stump, which arrested the hemorrhage, but it soon returned. He then tied the femoral just at the osseous neck, above the profunda, which was successful, and the patient recovered.

In dressing a stump, Dr. Moit has tried the plan of three or four stitches, and the application of cloths with cold water for the first day or two; but he greatly prefers to wait half an hour after all the vessels seem to be secured, for the occurrence of reaction, and, if there then be no hemorrhage, he adopts the old plan by antiseptic, adhesive straps, list, compresses, and roller.

Professor N. R. Smith, of Baltimore, reports in the *American Journal* of 1839 a case of peculiar interest, in which amputation of the thigh was successfully performed during progressive gangrene, resulting from a fracture of the thigh, in which the displaced fragment of the femur made pressure on the great artery and vein.

Dr. Nathan Smith, of New-Haven, performed

amputation at the knee-joint for the first time in America in 1824, and with complete success.

Dr. Parson, of Philadelphia, has recently amputated at the knee-joint for necrosis involving the head of the tibia; the integument of the leg, when so diseased as to leave no alternative but to remove the limb at the knee-joint, is amputate the thigh. He chose the former, and performed the operation for the third time in the country. The result has been most satisfactory. The patient bears her whole weight upon the condyles, a wire pad stuffed with hair covering her wooden leg, and the woman does the whole work of a maid-servant in a large boarding-house.

In amputations of the leg, Dr. Parson slopes the incision backward towards the posterior margin, about an inch higher than the median in the thigh. He has less fleshy skin, a better junction, less suppuration, and makes a better stump.

In amputating a leg far dry progress of the foot extending above the ankle, he found no necessity for a single ligature, the arterial trunks being closed with coagula and ligatures. The stump healed kindly, and the patient is well.

Dr. J. C. Cheseman, of New-York, has recently amputated twice at the shoulder-joint with success. This surgeon has also tied the external iliac artery for aneurism; twice removed the tibia for necrosis, and during the last two years has operated four times for strabismic laceria, performed twelve amputations of the thigh, eight of the leg, and three of the arm, in the New-York Hospital. The proportion of deaths after amputations have been, as at most of the other hospitals, about one fourth of the whole number. He has cured treated fractures of the thigh of long standing by extension at the ends of the bones.

Dr. Hæmer, of Philadelphia, has published an interesting paper on the subject of amputation at the shoulder-joint, with a description of new instrument for securing deeply-seated arteries. I regret that I can only make reference to the *Amer. Jour.* for 1861 for the important practical matter it contains.

Dr. J. Keamey Rodgers, of New-York, amputated at the elbow-joint with complete success in 1835, and Dr. Wagner, of Charleston, S. C., amputated successfully at the hip-joint a few years since. Dr. Murray, of Cincinnati, has been successfully amputated at the shoulder-joint.

Dr. Amos Prowbridge, professor in Wilkesby University of Lake Erie, has three times successfully performed amputation at the shoulder-joint. He claims to have been the first surgeon in the State of New-York who performed the operation. In this, however, he is mistaken, for his earliest date is 1850, while Dr. Rayle, of New-York, amputated at the shoulder-joint with success in 1792, and to him belongs the honor of being the first surgeon in America who attempted it. Professor Davidge, of Baltimore, repeated it soon after with similar success. Dr. Gibson has also performed this operation, and Dr. McClellan has repeated it six times with success. The latter surgeon has performed amputation at the neck of the thigh bone with success. Dr. J. Rhin Barton, of Philadelphia, has amputated at the shoulder-joint with success at least Dr. Gibbon, the latter as early as 1851.

Dr. N. R. Smith has performed amputation of the lower limbs more than fifty times, and has only lost five patients. Similar success has attended this operation in the hands of Drs. Moit,

Stevens, Barton, Gibson, Warren, and, indeed, all the leading surgeons of this country, many of them an extensive practice never having lost a single patient after amputation. If dismemberments have been witnessed in hospitals, according to Dr. Norris and Dr. Hayward, may it not in part be ascribed to the last haste in which amputations of limbs are too often performed in public practice, and often upon patients whose members would be preserved, or, at least, the attempt made to preserve them, if the cases occurred in private practice? That unnecessary amputations, or those of even doubtful expediency, are more likely to prove fatal than those which are imperatively demanded, does not admit of a doubt among practical men.—Raines.]

[ANAPLASTIC OPERATIONS. Anaplastin or autoplastin operation is the generic name which has been given to the restoration of lost parts, by the transplantation of cutaneous or subcutaneous flaps from adjacent sound parts, and relying upon the adhesive inflammation for effecting union, a portion of the transplanted integument being allowed to remain, by which the circulation may be carried on.

Of these operations several varieties have been reported to me by American surgeons, and I have in several instances witnessed their success. Dr. John Mason Warren, of Boston, has distinguished himself in this department by the number and by the success of his cases, some of which are reported at length in various periodicals.

Under the head of Rhinoplastic, it will be seen that Dr. J. M. Warren has employed dissection in the case, or, one time adopting the Indian method, by borrowing the flap from the forehead, and at another a modification of the Italian operation of *Telaezoni*, in which the skin is taken from the arm. His modification consisted in dissecting the flap from the forehead instead of taking it from near the insertion of the depressed muscle; a course which has many advantages when the flap desired is not larger than can readily be obtained from this locality.

Dieffenbach, of Germany, has perhaps done more than any other operator to revive anaplastic surgery, not only in his own country, but in France; for, on a late visit to that country, five weeks to the hospitals of Paris was afforded him, for practising the different species of operations for the restoration of lost parts. The brilliant success of Dieffenbach, Gaffie, and Lant on the Continent, of Linton in Great Britain, and Warren in the United States, has astonished the surgical world by the extent to which the different modifications of autoplastin operations are adopted.

Among the most important of these may be named the restoration of the lower lip and eyelid, after the excision of cancerous tumors, frequently practised by Dieffenbach; the closure of fistulous openings of the larynx and trachea, the vagina and urethra, &c., &c. The autoplastin method most generally adopted as applicable to these cases is that in which the flap required is taken in the immediate neighborhood of the part destroyed, then slid along, and confined in the desired situation by the twisted suture. This is what the French writers call "*autoplastin par glissement de lambeau*." Dr. Warren has repeatedly succeeded in this operation, for the removal of frightful deformities, and for supplying lost parts.

Dr. Mott, of New-York, has performed suc-

cessfully the rhinoplastic, geniofacial, lipoplastic, and urethroplastic varieties, for supplying a loss of substance by the transplantation and adhesion of sound integument upon the nose, cheek, eyelid, and urethra, as the names given to the several operations will indicate.

Dr. March, of Albany, has had complete success by the Indian method in two cases of rhinoplastic, and several other American surgeons have claims in this department, particularly Dr. George McClellan and Dr. T. D. Mutter, of Philadelphia, the latter of whom has had extensive opportunities in autoplastin surgery.

Under the article Staphylomyia, it will be seen that Dr. J. M. Warren has had extraordinary success by adapting this autoplastin method to the cure of congenital fissures of both the hard and soft palate. The soft palate having been prepared for simply largely by the usual ablation of its edges and the introduction of the necessary points of suture, the mucous membrane covering the roof of the mouth was carefully raised on each side of the fissure in the hard palate, and when thus detached, they were brought across the fissure and united like the soft palate by the interrupted suture, the flaps formed by the mucous membrane of the mouth being continuous with the detached edges of the soft palate. Thus, by a judicious union of staphylomyia and the staphyloplastic method, these shocking deformities are brought within the reach of surgery, even when there is extensive separation of the bones. In this operation Dr. Warren has done honor to himself, and earned this laurel for American surgery.

For the successful application of this operation to the lower eyelid by Dr. Warren, of Boston, Dr. McClellan, of Philadelphia, and Dr. Post, of New-York, see article *Rhinoplastic*. Dr. McClellan has also performed urethroplasty, geniofacial, and otoplasty. In the latter case the external ear was turned in the adhesions of the cicatrix following a wound of the head, and the deformity was amended by dissecting out the outflange, and elevating it to its normal position by flaps taken from the adjacent integument.

Dr. Frazer has thrice succeeded with rhinoplastic, and has applied the autoplastin method for restoring the upper and lower lip, and for contractions of the mouth, and has repeated lipoplastic, urethroplasty, and cheloplasty several times with success.—Raines.]

[ANCHYLOSIS.—The following article having been re-written by Mr. Cooper, is deemed worthy of quotation entire.

ANCHYLOSIS (from *ancklos*, crooked). True or complete anchylosis signifies the fixed and immovable state of a joint, resulting from the articular surfaces being consolidated together by osseous matter. False or incomplete anchylosis denotes the loss of motion, or very considerable rigidity in an articular or gimbal joint, occasioned by adhesions of one synovial surface to the other, or by a thickening of the soft parts on the outside of the joint. By Mr. Mayo, anchylosis is divided into osseous, cartilaginous, and serous, according as the articular surfaces happen to be united through the medium of bone, of cartilage, or of both these substances together. (See *Outline of Human Pathology*, p. 72.) Of course, this last classification is not intended to comprise some of the varieties of false anchylosis. True anchylosis, then, may be said to denote an intimate osseous consolidation, either of the kind of joint termed diarthrosis, where the

ends of the bones are tipped with cartilage, and furnished with a capsular ligament, or, at the other less movable sort of joint, termed symphysis, where the bones are united by an intervening layer of fibro-cartilage, and the articulation is strengthened externally by ligamentous bands. The latter kind of joint can hardly be said to be susceptible of true ankylosis, for it naturally has only a very slight degree of motion, which requires a true ankylosis for its termination.

Ankylosis is more common in the zinguloid articulations than others, though sometimes met with in every description of joint. In general, only one joint is ankylosed in the same individual; but sometimes several articulations are the seat of ankylosis, and rare instances are recorded in which every joint in the body was in this state. Thus, Bernard Connor describes an example of a general ankylosis of all the bones of the human body (*De stupido Ossium Coactu*). The particulars of a child, twenty-three months old, afflicted with universal ankylosis, are given in *L'Hist. de l'Art. des Sciences*, &c. 1718. In old age, ankylosis in certain parts of the skeleton is a natural elongation; and at this period of life it is common to find the heads of the ribs ankylosed to the bodies of the vertebrae, or the tubercles to the transverse processes, the vertebrae to one another, the epichondri cartilage to the scapula, &c.

Ankylosis, strictly speaking, is not a disease itself, but only an effect or consequence of other affections, and it may follow all those which destroy any one of the conditions, without which the motion of a joint is necessarily interrupted, either permanently or for a very considerable time. The author of the article *Ankylosis*, in the *Encyclopædie Méthodique*, refers to a preparation, in which the humerus is so ankylosed with the scapula and clavicle, that both the compact and spongy substances of these bones appear to be common to all of them, without any line of separation being discernible between them. Eustachius, Columbus, and Cruveilhier, have each seen an ankylosis of the lower jaw. In the Museum of the London University is a specimen of ankylosis extending to eleven vertebrae. In the same collection are examples of ankylosis between the occipital bone and the atlas, between the atlas and the dens, and between the three upper cervical vertebrae. There may also be seen perfect ankylosis of the three bones of the knee, those of the elbow and hip, of the metacarpal bones to one another, and of the scapula to the os humeri. Cruveilhier has given the particulars of an ankylosis of one of the articulations of the lower jaw in a very old woman. It commenced in her childhood, from a blow on the side of the face. From the ankyrosis of the parts, it appears that the condyle and glenoid cavity were completely consolidated and filled by osseous matter.

Referring to ankylosis in general, we may observe with M. Sanson, that its causes are numerous, inasmuch as every circumstance capable of impairing the articular surfaces, stopping the synovial secretion, lessening the suppleness of the ligaments, or of the soft parts around the joint, and interfering with the action of the muscles or the play of the tendons, may hinder the articular surfaces, more or less, from moving upon one another. One thing, almost essential to the production of ankylosis, is the part being kept motionless; and, as M. Sanson well ob-

serves, this condition has such influence, that it will of itself bring on the changes which terminate in a joint becoming incapable of resuming its function in consequence of true or false ankylosis. An illustration of this fact is afforded by what happens to the Indian fakirs, who, by way of religious penitence, sometimes condemn themselves to continue motionless in certain attitudes for several years, and whose limbs at the expiration of the term are ankylosed in the posture in which they happen to have been as long maintained. The same fact is exemplified in persons who have met with fractures of their limbs, &c. in consequence of the motionless state in which the part is kept to promote union of its broken bones, the synovial secretion is diminished, and the fibrous connective and ligaments of the joint all acquire a rigidity in which the surrounding cellular tissue participates. The elasticity of the tendons are also no longer any advantage. All these circumstances make opposition to the free action of the muscles, which, being thus deprived of their natural elasticity, are incapable of overcoming the resistance to the motion of the joint. On the same principle, a long continued motionless state of an articulation, ankylosis may be induced as a consequence, and sequel of the contracted state of some muscular vessels, or of the growth of various tumours near the joint. The contraction of tendons also takes, or after a destruction of the soft parts by gangrene or ulceration; and in impeding exit of the cellular tissue, the effect of extension and moderate abrasion in it; certain tumours, and especially inflammation of the synovial membrane, whether acute or chronic, idiopathic, ankylosis, or rheumatic, &c., or accidentally excited by mechanical injury of the joint, are all so many circumstances capable of leading to ankylosis. Particular fractures of the joints, or such as are situated near them, if not skilfully treated, are apt to be followed by inflammation of the synovial membrane, absorption of the cartilages, and complete ankylosis. No doubt, in some of these instances, the connective ankylosis at first only to what authors understand by false ankylosis; but, in the course of time, this becomes converted into complete or true ankylosis, terminated by osseous consolidation. On the whole, however, as M. Sanson has remarked, false ankylosis is far more common than the true form of it.

When a bone is fractured near a joint, and this is kept too long motionless, ankylosis is apt to follow. Here the risk is increased by the synovial membrane being freely inflamed; and, indeed, sometimes the accident brings on ulceration of the cartilages. In the North London Hospital, I lately saw a case where the ulceration had been broken across its base, and the detached pieces had become completely consolidated in the bursæ; yet the patient had great exertion power of extending the forearm, motionless through the medium of the long supinator and other muscles arising from the outer condyle. It is partly in consequence of the risk of inflammation of the synovial membrane and of ankylosis that fractures of os very near joints are now seldom treated other differently placed. Wounds and contusions of joints may bring on such changes as terminate in ankylosis. I have already mentioned that Cruveilhier has seen an instance of ankylosis of the right articulation of the lower jaw. This was brought on by a blow received on the part when the patient (a female)

was a child. She lived to a very advanced age, and, notwithstanding the ankylosis, was able to speak very well, and to maintain by passing the food with her tongue, during the hard substance covering the alveolar process, where the teeth were deficient." (*See Greenough, Anat. Pathologica, lxxix. pl. Symp. 3 and 2.*)

With regard both to true and false ankylosis, the surgeon may generally render good efficient service in preventing, that in consequence to cure them. In wounds, contusions, and lacerations of new joints, the best means of prevention consist in the previous addition of the hyaline treatment at first, and of a later stage in having closely pressure to pressure margin of the joint, and then to substitute with this plan fixation with unabsorbent and other liniments, in order to promote the formation of the synovial. When the bones are exposed, as in syphilitic disease of the vertebrae, and in advanced stages of ulceration of the parotids of the knee, elbow, wrist, &c., the hyaline method of excision, to prevent ankylosis, should possess its secondary, as the most favourable result, which the case requires. In fact, the excision of ankylosis, well-timed, the indication of the disease, the important position, however, under high circumstances, to let the limb be ankylosed in the position where will allow it to be of the greatest possible use. Thus, when the elbow is likely to be the seat of ankylosis, the hyaline should be kept less than when the knee is concerned, the use should be kept extended, and when the hip, the thigh should be maintained in a similar position. If ankylosis should have taken place to a certain extent, with the limb in a disadvantageous position, this may often be still very much improved by the application of splints, and other mechanical appliances. The action of any mechanical appliances, however, must be applied moderately, through stimulating. Perseverance will here succeed when violence would fail by bringing an already painful a disorganized degree of inflammation. Indeed, when the attempt to remove a false ankylosis by gentle passive motion, enemas, and the cautious use of mechanical means, fail, it is better not to employ violence, because such an ankylosis is preferable to inflammation, abscess, and ulceration of the joint.

As for true ankylosis, where a complete osseous consolidation has taken place, it may be set down, not only as incurable, but as obligating of no improvement or absorption in the position of the limb, and, whatever that may be, the patient must be content with it. Hence, where there is risk of ankylosis, the great importance of placing the limb in position is the position which will be of the greatest service to the patient.

Mr. Barton, one of the surgeons of the Epsom Hospital at Philadelphia, made, a few years ago, the bold attempt to cure an ankylosis of the hip-joint by a surgical operation. (*See North American Medical and Surg. Journ. for April, 1827.*) The patient was a young soldier, who had fallen into the hands of a shipwrecked man, and remained seven days without surgical assistance. He was now admitted into the above hospital, under Mr. Barton. The injured thigh, which was the right one, was in the best position, with the knee drawn across the lower part of the left femur. The inside edge of the foot was placed forward, and the sole turned outward. A suspicion of dislocation was im-

mediately entertained; but, so great was the swelling, and so acute the pain in the hip, that Mr. Barton was deterred from making a digital examination to ascertain the fact. As soon as these symptoms had subsided, the limb was kept for several weeks extended in an apparatus, but without producing any absorption, or change in its position. Indeed, a complete ankylosis between the femur and os ilium had taken place. After a year's consideration, Mr. Barton, seeing that the case was beyond all common means of relief, determined to attempt to make an artificial joint. For this purpose, he made in the upper part of the thigh an incision six or seven inches long, the middle part of which corresponded to the great trochanter. The centre of this last cut was crossed by another four or five inches in length, at a right angle. These incisions divided, at intervals, the skin, the fascia, and muscles, so as to expose the articular and posterior part of the femur, between the great and little trochanters. The femur was then sawn through, between the great trochanter and the neck of the bone. The operation was completed in seven minutes; and, at once as it had been done, the limb was easily brought into its proper position, and, and could not to be more than about half as much shorter than the other. The wound, which had by itself, was now closed, and the limb put up in a suitable apparatus, with one of Boggan's screws. At first the inflammation, swelling, and inflammatory fever were so severe, but in ten days these symptoms abated, and the wound suppurated favorably. Suffice it to add, that the patient could move his thigh in all directions, and was able to get up; and in four months he was able to walk a considerable distance. He could, by this time, move the foot twenty-four inches forward, twenty-six backward, and twenty laterally, and flex it six inches inward or outward. The limb was strong, had so much shorter, that the patient walked very perfectly. Before the new joint was a deposit of bone, securing the femur in this position, and preventing its dislocation. Although the successful result of Mr. Barton's operation is what his colleagues fully deserved, I agree with Mr. Simon in thinking that doubts will be entertained by many judicious surgeons whether the proceeding, which actually put the patient's life in jeopardy, was really indicated.—O.

(Notwithstanding the opinion expressed by Mr. Cooper and Mr. Simon, adverse to the surgical competency of Dr. Barton's successful operation, while they commended its ingenuity, boldness, and success, this same gentleman has raised for himself and the profession new laurels by another and original operation for the removal of a shocking deformity of the knee-joint by ankylosis, the knee being bent at right angles with the thigh. A full report of the case may be found in the *American Journal of Medical Science*, and cannot fail to excite the admiration of the surgeon, would as a brilliant illustration of the triumph of our art.

A free incision being made with the anterior and inferior portion of the thigh, exposing the femur a short distance above the knee, Dr. Har-
sham proceeded with the saw to make an angular bottom of the bone, the apex of the triangle being near the posterior surface, carefully preserving the continuity of its shaft by leaving a thin ledge of the os femoris still attached. The triangular portion being removed, two cut surfaces

of bone were lost, with a ragged increasing in width from the apex to the base of the triangle. These two surfaces were gradually approximated, aided by suitable incisions, and as they approached each other, the leg was extended until the union of the two bony surfaces being accomplished, the limb was brought down to a position occupying very little deformity or inconvenience, and adopting it to all the purposes of locomotion. Complete recovery attended this new and original improvement in surgery.

Dr. J. Keeney Rogers, of New-York, reports an operation for aneurysm of the hip-joint, suggested by the stimulus of Dr. Hunter. "An incision was made down to the os femoris, and this being secured through immediately above the trochanter major. The limb, which had been greatly abducted, was powerfully placed parallel with its fellow. But, as it was desirable to shorten the limb to conform to its fellow, which had been shortened by a fracture, another incision was now made with the saw in the femur, and a wedge-shaped portion removed. The result of this operation was as gratifying to the patient as it was creditable to the surgeon who executed it. Two years afterward he paid a visit to Dr. Rogers to express his gratitude for the restoration of his power of locomotion.

Dr. Guerin, of Philadelphia, has lately performed a similar operation to the second case of Dr. Hunter for aneurysm aneurysm of the knee-joint. This case, which was completely successful, is reported at length in the *American Surgeon* for July, 1842.

FALSE ANEURYSM OF THE KNEE-JOINT.

In the *American Journal of the Medical Sciences* for January, 1843, p. 101, Dr. Harker Chase has given the history of several cases of false aneurysm of the knee, cured by means of rest and gradual extension upon an apparatus with a screw and joint at the knee, similar to those recommended and employed by Mr. Lisson of London, and Dr. Detmold of New-York. The results of Dr. Chase tend to show that in most cases false aneurysm of the knee, with appreciable motion of the joint, is readily curable in a reasonable time without the aid of amputation, and without material pain to the patient. The straightening of the limb has been effected in every instance, and the free use of the joint has been ultimately regained in the majority of cases. It is found absolutely necessary to secure, and the prevention of progress, that the limb, when properly extended, should be retained in that attitude from one to two months before even commencing the passive or voluntary motions necessary to give free play to the articulation. — *Review.*

[ANEURISM. An aneurism may be defined to be a tumour filled with blood, either in a fluid or solid state, usually attended with pulsation, and the seat of which has an opening in it, by which it communicates with the artery, from which the blood is transmitted into it. Celsus defines it "a tumour formed by arterial blood, and communicating with an artery," and divides all aneurisms into traumatic and spontaneous, according as they happen to be produced by a wound, or disease of the coats of the artery. (*De Cognitione et Anore etia de Aneurismo*, p. 6.)

Mr. Cooper has placed the following in his *Annals*:

Since this article aneurism was printed, the artery aneurysm has been tied by Mr. Lisart,

but with the same unfortunate success as had followed all other examples of this operation. Under these circumstances, could the practice be continued? I think not, especially did the evidence in favour of tying the cord.

Subsequently to the period when the article Aneurism was conceived, Mr. Lawson, a skilled vascular aneurism, created very close to the upper edge of the right scapular artery, (the right scapular artery and right axillary artery) aneurism, by which means it was hoped that the aneurism would become completely plugged up with coagulated blood, and the artery would have a better chance of being permanently closed than if a ligature had been applied to the much larger vessel, the axillary itself. The aneurism was made by Mr. Lawson. In fact, proximity to the patient's death had been hastened, on the basis, they show the aneurism, the aneurism before perfectly plugged up with solid blood; the ligature had come away from the vessel, and was found lying loose in the wound, with the two ends of the artery above and below separated by an interval of more than an inch, and permanently closed. The ligature on the artery had not separated, and the rest of that vessel, on the side towards the heart, was closed; and the aneurism had taken place from an ulcerated opening in the vessel of the artery on the distal side of the ligature. My friend Sir Astley Cooper, Mr. Wilson, and some other surgeons of great experience, have noticed also, when secondary aneurism occurs after operations for aneurism, it is most frequently produced by ulceration of the vessel on the distal side of the ligature.

When an aneurismal sac is formed upon a blood-vessel, the walls of the vessel are sometimes thinner than usual; and some parts of them are become expanded into pouches, or even ruptured upon the internal walling, the protruded points being always the thinnest. This kind of case is sometimes termed a *ruptured aneurism*, of which there is a good specimen in the *British collection*, remarkably also as exhibiting an aneurism opening by ulceration into the pulmonary artery. (*See British Ann. of Anom.* p. 55.)

Aneurism, by dilatation is distinguished by Broussais into four varieties, the names of which are distinguished by the differences in the stage of the expansion of the arterial tube. For instance, 1. *The aneurism of the artery*; 2. *The false aneurism*; 3. *The aneurism of the artery*, attended with rupture of the large arteries and the end of the small arteries, or the aneurism by rupture of the artery, and the artery of the artery; 4. *The aneurism of the artery*, or aneurism of the artery. In aneurism of the artery the vessel has at one point of its circumference a small sac, consisting of an expansion of the arterial tube. This variety is least frequent in the artery, but sometimes on the carotid and the artery, and even on those of the brain. In this aneurism, all the arterial tubes are simultaneously dilated; but as the internal and middle coats have but a limited degree of extensibility, the aneurismal aneurism does not generally exceed the size of a filbert, though Broussais has noticed some on the artery as large as a hen's egg. (*See Broussais, de Différence Rapports d'Aneurisme*, p. 12, &c.)

In the *false aneurism*, the dilatation extends over the whole circumference of the vessel; all the coats participate in it. The calibre of the artery, after losing its order and wider

gradually for a certain portion of the trunk of the vessel, then tapered in a narrow equally gradual, till it has resumed its natural diameter.

The cylindrical aneurism of Broussier might be regarded only as a variety of the fusiform, inasmuch as an abrupt transition from a given calibre to a much more capacious one is never observed. Yet, according to the investigations of Broussier, cases present themselves in which the artery is uniformly dilated through a track of one or two feet, the cylindrical form being here strictly preserved. Their pathological fact has been noticed by Broussier in the arteries of the limbs, and in those of the brain and of the cranial cavities. (*Op. cit.*, p. 35.)

In the true aneurism, however, the artery is described by Broussier as being not only dilated, but tortuous, and constantly stuffed with small arterial funnels. The parietes of the vessel are thin and collapsed, while, in the other case, they are rather thickened. Such is Broussier's classification of true aneurisms; a classification which, considering as it does, aneurisms by intussusception and cerebral aneurisms, and those of different kinds, presents a great deal of novelty.

CAUSES OF ANEURISM.

An aneurism will not follow the kind of weakness of its walls which most necessarily arises from removing its external and middle coats, some morbid changes having to be assumed to bring on a protrusion of the inner coat. Neither will a mechanical distention of the tube suffice to lead to an aneurismal dilatation of the future coat. The latter fact is proved by what happens when a tight ligature is placed upon an artery, as well as by the experiments of M. Arnould, who purposely broke the internal coats in numerous places by passing the vessels with forceps, and detaching the inner coats from the outer by a process somewhat similar to what he adopts in torsion of the gutters. By perseverance of this kind, he never succeeded in producing the beginning of an aneurism. The inference therefore is, that some distention of unusual degree in the coats of the artery is necessary for the formation of aneurism, so long as the occurrence is limited by a perfect state of any of those coats; or else the most active of the still more active conditions, that in the experiments undertaken by Hume, Arnould, and others, the laceration of the artery was followed by inflammation of it, coagulation of the blood, and such an effusion of fibrine within and around it as would fully atone for the structural laceration being the result.

One very interesting point in relation to aneurismal aneurism, and particularly observed to by M. Malgaigne, is the almost exclusive restriction of this disease to the aortic system. Thus it is rare that three hundred aneurisms observed by M. Lédér, or recorded by others, be met with only two instances of an aneurismal disease of the pulmonary artery; and these are free from objection. (*Leçons de Médecine Malgaigne, &c.*, par M. Lédér, de Paris, p. 8, 8ra, Paris, 1844.) This remarkable fact is supposed to depend upon the aortic arteries containing between their inner and middle coats, a dense, hard, fragile tissue, very capable of being taken off in scales, and described by M. Malgaigne as the sclerous coat. When aneurisms of different kinds, calcareous, aneurysmal, or catarrhal, present themselves in the aorta, they are meted, according to M. Malgaigne, almost

exclusively to this sclerous coat; a feature not existing in the pulmonary artery or its branches.

Both the external and internal of the same individual were tied in succession by Mr. Tait, one on the 9th of May, 1855, and the other on the 16th of April; and this with entire success, notwithstanding the pentimento was wounded in one of three operations. M. Arnould also took up both the external and internal in one patient, and, though there was only an interval of a week between the operations, the case had a very favourable termination. (*See Volcan, Nouv. Élém. de Méd. Opér.*, t. i., p. 178.)

The operation of tying the internal aorta was also performed by Mr. Thomas, of Bordeaux, who sent the preparation of the parts to Sir Astley Cooper, and it is in the Museum of Guy's Hospital. (*Med. Chir. Trans.*, vol. xvi., p. 230.) A high instance of the application of a ligature to the internal iliac artery took place in the practice of Mr. Hudson, of New-York. (*See American Journ. of Med. Science* for Feb., 1858, vol. v., p. 304.) A small aneurism, seven inches in length, was made, with the economy towards the limb, from the vicinity of the umbilicus to that of the adductor ingu. After dividing the parietes of the aneurism, and tying some arteries, which tied the pedicle, the aneurism was pushed upward and inward, and the handle of a scalpel passed under the trunk of the internal iliac artery, which was tied in such below its origin. The patient recovered.

It is very justly observed by M. Volcan, that the ligature of the internal iliac artery, with regard to its influence on the circulation, is infinitely less serious than that of the external iliac, or even the femoral. In fact, it leaves undisturbed all the vessels springing to the corresponding limb, while the great pelvic arteries anastomose with one another so freely, that, when one is diminished, an abundance of blood is promptly conveyed by the others to the organs which the diminished one is designed to furnish. But the feature of the internal iliac artery is dangerous in another point of view: first, on account of the difficulties in its performance; and, secondly, on account of the unavoidable detachment of parts from one another, which are connected together by a large quantity of loose cellular tissue, a texture in which inflammation and suppuration are disposed to spread to a great extent. (*See Volcan, Nouv. Élém. de Méd. Opér.*, t. i., p. 185.)

On the subject of tying both carotids, I find some interesting observations made by my friend Mr. Casson. "Although (says he) some animals will bear a ligature to both carotids simultaneously, the human frame cannot sustain so great and so sudden an interruption to the supply of blood to the aneurism. Professor Moit has tested this question; and a case came under my own observation very recently, showing the full tendency of a ligature if applied almost simultaneously to each of these arteries. An approximation has, however, been made towards ascertaining the shortest interval at which the second carotid may be tied, others become to the first; and it has been safely done at an interval of thirty-eight, seventeen, and even twelve days. Among the most striking of these cases is that related by Professor Kuhl, of Leipzig, who, on account of a pulsating aneurismal tumour of the scalp, exposing near a wound of the occiput, and extending over nearly the entire surface of the

head, attended by frequent hemorrhages, first placed a ligature on the left common carotid. This proceeding only partially relieving the disease, and frequent hemorrhages from the affected portion of the scalp still occurring, and threatening life, a ligature was put upon the right common carotid after twenty-seven days. This was followed by convulsions; but after a train of very troublesome symptoms, the patient recovered, and was cured of his disease. It is worthy to be noticed, that in this, and also in other like cases, some days after both carotids had been tied, heaviness and throbbing in the head have occurred, requiring free evacuation." (*J. Med. Assoc. Trans.*, vol. 9.)

Guthrie has met with but three popliteal aneurisms in women; and he calculates aneurism of the limb occurs both twenty to thirty times in men for once in women. "The structure of the vessels (he observes) is the same, but the mode of life is different. The operation in general is infinitely greater in the man than the woman; and I think this, combined with the first use of arterial spirits, a much more salutary course than either aphlebia or mercury." (*On Dis. of Arteries*, p. 75.)

In relation to the comparative frequency of aneurism in the two sexes, M. Liston states that, in 134 cases, the particulars of which have been collected by him, and whose attention he directs them within the reach of operative surgery, the proportion of male patients was 10; of females 24, or nearly 11 to 1.

With respect to the comparative frequency of aneurism in different arteries, M. Liston refers to 179 cases, all aneurisms; those of the parts not entering into the computation, from which 179 cases he gives the following table:

1. Popliteal artery	59
2. Femoral $\frac{1}{2}$ in the groin	26
3. Carotid $\frac{1}{2}$ at below points	16
4. Cerebral	17
5. Subclavian	14
6. Axillary	14
7. External iliac	5
8. Brachiocephalic	4
9. Brachial	3
10. Common iliac	3
11. Anterior tibial	3
12. Gluteal	2
13. Internal iliac	2
14. Temporal	2
15. Internal carotid	1
16. Ulnar	1
17. Peroneal	1
18. Radial	1
19. Palmar per	1

[Dr. Valentine Mott, of New-York, has tied the common carotid artery twenty times. In two cases it was the distal operation for aneurism of the internal carotid, and in one of these was successful. In these instances he has thus cured aneurism by anastomosis. In two examples both of the common carotids were tied in the same patient; in the first case, the interval between the application of the two ligatures was about twenty minutes, the patient dying suddenly on the second day after; in the second case, a year elapsed between the first and second operations. This case was a large aneurism of anastomosis, occupying the temporal and parotid regions, extending deep about the articulation of the lower jaw. In the removal of the parotid gland, Dr. Mott found it necessary, in one case, to tie the external carotid at the point between the styloid

muscle and the larynx nerve, an operation the difficulty and hazard of which every surgeon will know how to estimate. The same surgeon has repeatedly tied the external carotid over an artery in his operations for aneurism.

The same surgeon has also tied the subclavian four times; once within the axillary vessels of the right side, three from secondary hemorrhage; three times within the axilla, all successful in curing axillary aneurism.

Dr. Mott was the first surgeon in the world who successfully tied the common iliac artery, and this year for a large aneurism of the external that near the femur. Dr. Severance, of St. Petersburg, has since performed it with success.

This operation was performed by Dr. Mott on the fifteenth of March, 1827, and the case reported soon after in the *American Annual*, No. 1, p. 156. Nearly seven years afterward, the *Medical Champion*, Review announced the successful result of the case in which Mr. Guthrie applied a ligature to the same artery, and the same result, pleasantly observes.

"Thus this most formidable aneurism has been successfully performed for the first time, and while it adds a strength of belief to the views of the distinguished surgeon, it constitutes a splendid triumph of British surgery."

Dr. Hays, of the *American Journal*, in republishing this number of the *Lancet* reviewer, remarks that this "triumph of British surgery" belongs to this side of the Atlantic, and that it has placed the surgery of aneurism not distant to write their. He then adds, "The distinguished surgeon to whom the British public belongs is our colleague and countryman, Dr. Mott, who, upward of seven operations, successfully applied a ligature to the common iliac."

The British reviewer, again, in regard to remarking that this "successful" operation of Mr. Guthrie was very well tied, and he strongly fails to record the fact that the aneurism for which Mr. Guthrie tied the common iliac turned out to be a malignant fungus, which the operation decided to be aneurism, and the patient was dead, when the mistake of his position was discovered. This record, however, would have withered the wreath of laurels upon the brow of Mr. Guthrie, and deprived British surgery of this splendid triumph.

Fifteen years have now elapsed since Dr. Mott's operation, and the progress is still going. And yet Mr. Guthrie himself, in his work

"On the Diseases and Injuries of Arteries," p. 265, records this case of Dr. Mott as lost, although he extracts his account of the operation from the *American Journal*, in which the same statement of the patient to which is again mentioned.

Dr. Mott has also tied the external iliac six times; of these, five were successful, and one failed. The first of the four cases was from secondary hemorrhage, but the second died of pneumonia, from drinking to excess shortly after the operation. He also tied the internal iliac in 1831 with success, for a large aneurism in the region of the sciatic notch, and the patient is still living in perfect health.

Dr. Mott has tied the femoral artery five times, and in only one instance has secondary hemorrhage taken place. In this case the patient had a popliteal aneurism, and, after the failure of the ligature on the femoral artery, he secured the external iliac; but, on the evening after of the ligature, secondary hemorrhage

again occurred, and was ultimately fatal. This was a fair case for tying the artery, and Dr. Mott was only concerned by the marked stage of the arterial by-pass, as was ignorant in the result of the two ligatures, which had been successfully only on this account.

Dr. Mott has noted one of my citizens of a double aneurism, confined to the thoracic and femoral on the other very high up. He told for the femoral the femoral artery, and on the latter the external iliac. The patient is still living in New-York, and in prime health. The same surgeon has tied the tracheal, vena, renal, uterine, and posterior tibial for wounds, tumors, and other, renal disease a great number of times with uniform success.

The left primitive iliac artery was tied for aneurism of the external iliac by Dr. Alfred C. Post, at the New-York Hospital, on the 25th of August, 1844. The case terminated fatally. An account of it is published in the New-York Journal of Medicine and Surgery, October, 1844.

Dr. George McClellan, of Philadelphia, tied the common carotid three or fifteen times for aneurism and tumors. He has also successfully tied the subclavian three times, the external iliac three times, and the glenoid once.

Dr. N. K. Smith, of Baltimore, has tied the subclavian artery, the external iliac, the carotid three times, and the femoral eleven times for aneurism. The same surgeon has had occasion to tie the internal jugular vein, which he effected successfully, and the patient recovered.

Dr. Allen Goldsblith, of New-York, has tied the subclavian twice the axillary artery, and in one of the cases he has had entire success. He has also tied the carotid three times for aneurism by anastomosis, which was cured, and for tumors, which were afterward successfully extirpated; but he declares in the opinion that tying the vessel does not remove the blemish. In such operations, aneurism never reformed.

Dr. Penco, of Philadelphia, has successfully tied the external iliac for aneurism in the Pennsylvania Hospital.

Dr. Penco, of Philadelphia, has had occasion several times to take up the carotid artery in cases of aneurism at the neck by cutting the throat. He has observed that, in these cases, where there is much enlargement of blood supply the parts, the dissection need not be so large as when the vessel is not so large, and that the procedure will depend on the size of the vessel.

Dr. Penco has devised a method for the purpose of tying the subclavian artery below the clavicle, which will render the operation less difficult upon the living subject. He opens the space between the axilla and clavicle, and then divides the pectoralis major muscle, and then divides the external pectoral artery, and ties the clavicle over the artery. He then brings the divided portion, and holds for the artery beneath.

He has operated the same for aneurism at the base of the arm by tying the axillary artery with a small ligature just below the axilla, and below where it is crossed by the median nerve, leaving the nerve undisturbed. The cases were all recent, and the operation successful. In some cases, which are of long standing, he attempts to open the sac and apply two ligatures.

Dr. P. has also taken up the femoral artery twice with success for popliteal aneurism. He has also tied the stylo-mastoid artery for false aneurism, recovered by ligature. The patient

was a quack doctor from the West, who tied himself, and was in the habit of bleeding his patients at the carotids. The neck had burst, and aneurism had taken place. A single ligature effected, but the operation must be a difficult one, when we remember the proximity of the communicating branches of the facial and great auricular nerves, which are parallel with the stylo-mastoid artery opposite the lobe of the ear.

Dr. Deane, of New-York, has recently tied the common carotid for aneurism by anastomosis, involving the whole side of the face in a lady who was thirty-eight years of age, and at the time the aneurism was very rapidly increasing. The growth was checked immediately, and the aneurism is fast closing, and of the nature of the aneurism of the difficulty will be the result.

Dr. N. E. Smith, of Baltimore, reports a case of temporary paralysis following a ligature upon the external artery. As this aneurism result did not occur immediately, but after an interval of some twenty hours, and as it was relieved, and the patient recovered by full restoration, the aneurism was attributed to the weakness of the vessels not destroyed, giving rise to muscular degeneration, and was indicated to be the true pathological state by the symptoms. (See *Medical and Surg. Jour.* for 1845.)

Dr. McCreary, of Cincinnati, reports a case of aneurism of the carotid artery, situated with the artery, and for which he tied both of the common and primitive trunks, after an interval of twelve days. The distention of the carotid and expansion of pulsation, which induced a severe hope of success, proved to be but temporary, and six weeks after he was obliged to expose the whole mass by an incision around its base, and which exposed forty ligatures. The patient completely recovered. (See *Amer. Jour.* for 1838.)

Dr. Harvey, of Philadelphia, has published in the American Journal for 1841 an accurate and highly valuable report of two cases of aneurism, exhibiting the necessity of a ligature both above and below the tumor.

In the American Journal for 1837, Dr. Morris, son of Thomas Ayres, reports six cases of aneurism cured by operation, the details of which are honorable to this surgeon, who was graduate of the University of Maryland, and his paper will be found to be highly interesting to the student of this branch of surgery.

Dr. V. S. Kirkbride reports, in the American Journal for 1838, five cases of aneurism of arteries successfully treated by compression, illustrating the important fact that aneurism is often tied for spontaneous aneurism, when compression, judiciously applied, would succeed in preventing the necessity of the operation. In this way he has tied aneurism with the radial, femoral, and femoral arteries; and, after reporting the cases, Dr. K. adds practical observations on the general subject which are of great value.

Dr. J. R. Forster, of Philadelphia, has long distinguished himself in the department of treating vascular diseases by other means than the use of the knife, fully regarding the avoidance of an operation as more meritorious than the ligation of any artery of the body. So also in those cases and lesions for which amputation is often practiced, Dr. Forster's horror of amputation patients has led to the employment of his energy and skill in preserving the limbs, even when more difficult operations than amputation are indicated.

ted as necessary for the purpose. Under the head of Aneurisms I have alluded to an eminent instance of this variety.

In the *Ecliptic Repository*, vol. i, p. 203, Dr. Joseph Parry reports a case of femoral aneurism spontaneously cured. His son, Dr. Isaac Parry, relates a case of aneurism in the orbit, in the *Amer. Journ.* for October, 1810.

Dr. Paul F. Levy, of Georgia, has lately succeeded in curing an aneurism of the neck resulting from a wound of the brachial artery, made by transfixing the vein in phlebotomy. In this case the artery was ligated above the tumour without success. Six minutes afterwards Dr. Levy tied the artery on the distal side of the aneurismal tumour, but this operation, also failed, and the pulsation of the tumour continuing, he was led to treating the aneurism by placing two ligatures upon it at opposite points, and by this operation the tumour was completely obliterated.

Dr. Alexander E. Howard, of New York, has devised an instrument in which dissection is effected, which practical men regard as possessing great merit. An account of it may be found in the 2d vol. of the *N. Y. Med. and Phys. Journ.* with a drawing. The advantage of this instrument is, that after tying the first knot, the second may be brought down without disturbing the first, as there is no stress upon the ligature between the two. It has been found to afford great facilities in ligating the internal iliac, and abdominal aortae. See White's operations for pulsed aneurism, in the *Amer. Journal* for 1827, and also Dr. Gross's case, and remarks on the abdominal artery, *Western Journal* for 1841.

Dr. J. Keeney Rogers has tied the external iliac, the internal iliac, and the femoral in the same patient, for complicated aneurisms.

Under this head I have introduced into the text the only instance of the ligature of the internal iliac for the cure of pulsed aneurism ever performed in this country, as communicated by Dr. S. Percey White, of Hudson, N. Y., and it is there stated to be the fourth instance in which this operation has ever been attempted. I find, by a late number of the *Lancet* Gazette, that Dr. Thompson, of Manchester, has since performed this difficult operation, but without success, as would seem from the fact that a preparation of the parts has been sent to Sir A. Cooper, and is now in the museum at Guy's Hospital. So that this artery has now been tied five times; twice in the West India case in Russia; once in Great Britain, and once in the United States.

Dr. Steyens, of St. Cuth, was the first to attempt this hazardous operation, as may be seen by a reference to the article in this Dictionary. This case occurred in 1812, and was completely successful. The patient lived ten years after the operation, and, dying in 1826 of some other disease, an opportunity was afforded of examining the parts. "The preparation was sent to London to remove the skepticism of those who persevered in declaring the operation impossible. Still, however, a few distinguished men doubted the reports of the several cases, and Mr. Lawrence, in his lectures, still questioned the possibility of tying the internal iliac; and alluded to only one case in which it was said to have been performed. (See *Lond. Med. Gazette*, No. 124.)

During the present year Dr. Stensen visited London in the suite of the governor-general of the Danish West India islands; and having his attention called to the aneurism of Mr. Law-

rence, he immediately sent the preparation, which had been in London unstopped for several years, to the Royal College of Surgeons, where, in the presence of Mr. Lawrence, a minute examination was made, to the entire satisfaction of all present. It appeared, however, that the aneurism was not in the glided artery, as had been supposed, but in the great intestine; and Dr. Stensen suggests that this is probably the seat of the disease, in many instances, of what has been called glided aneurism.

Sir Astley Cooper has given a circumstantial account, after having carefully examined Dr. Stensen's preparation, which is also published in the *Gazette*, declaring himself perfectly satisfied of the existence of the aneurism, and the complete obliteration of the internal iliac. For, although this preparation has been in spirits eight years, "it still exhibits the internal iliac converted into an imperious chord whose ligature was applied, and whose very distinctly the pulsation of the aneurismal swelling in the external artery."

In the *Western Journal of Medicine* and Surgery for June, 1841, Dr. S. D. Gross, professor in the Louisville Medical Institute, reports a case of aneurism of the artery for which he tied the right subclavian artery. The patient died on the third day of the effusion of the contents of the aneurismal sac into the thoracic cavity, which had obviously resulted from ulcerative absorption of the walls of the tumour, and before any management before the operation. But for this untoward event, which success would have crowned the operation, for the ligature came away in due time, and the wound did well.

Dr. Gross relates the history of twenty-two cases in which this artery was tied, of which aneurisms were cured. He records three instances in this country, the first by Dr. Post, of New-York, in 1817, successful; the second by Dr. Gibson, of Philadelphia, in 1828, the patient dying on the eighth day; and the third by Dr. Mott, of New-York, in 1830, in which the patient recovered. So that it appears that in America the first instance of aneurism on record was furnished by Dr. Post; for, until his case, it had sided in the hands of Ramsden and Blinck of London, and Dr. Colles of Dublin, the only instances of this artery being previously tied. Thapsimus was the next to succeed, which he did two years after at the Hotel Dieu of Paris. The paper of Dr. Gross is an elaborate and meticulous criticism upon the whole subject, and does him great credit.

In the *Ecliptic Repository*, vol. iii, p. 223, Dr. Joseph Parry, of Philadelphia, has a paper on the application of a ligature to the abdominal artery, with description of instrument.—Hence.

[ANTRUM. COLLECTIONS OF MIST.]

In general, I believe that the extraction of one of the molar teeth will not prove very applicable to the present case. First, because the thick alveolar bone that requires a larger opening than can be thus obtained; and secondly, because, when the surgeon is called upon to perform an operation, the bony texture of the antrum is already very thin, much softened, or even partially dissolved above or behind the jaw, consequently, as easy as the surgeon has made an incision above the gum, or at the part of the swelling protruding itself on the roof of the mouth, he feels that a pulse will immediately follow the incision. All that he has to do, therefore, is to enlarge this opening with a pair of small bone-force, or a

strong knife. Mr. Hunter's apprehensions, respecting the difficulty of manipulating the opening, and of the likelihood of a return of the antritis, does not appear to be confirmed by what happened in the cases under Hunter and Sir Benjamin Brodie. The latter surgeons, as they, never dissecting the membrane of the cheek from the jaw, I think a curved scalpel, bent laterally, with a strong sharp point, and introduced the point into the angle of the thin fleshy part, or boundary of the tumour - immediately there escaped a large quantity of transparent fluid, like what we find in cases of antrum. I then introduced a probe into the cavity of the antrum, and found that it might be passed in any direction. There was neither tumour nor pain seen in it, and the cavity seemed to be in a natural state, except that it was somewhat dilated. I next enlarged the opening, cutting out a circular portion of this fleshy shell, formed by the expanded portion of the antrum. After the operation the tumour subsided, and in a few weeks the cheek was not larger than the other. The operation made by the scalpel has contained pusiveness this day, though it is ten years since I performed the operation. The lady wears a plug, which she takes out night and morning, and with her own hand introduces the point of a syringe, and washes out the antrum. (See *Lond. Med. Gaz. for Dec.*, 1834.)

APPROACHES TO THE ANTRUM.

The following way of making the opening is recommended by Sir B. Brodie: "Raise up the cheek, so as to expose the membrane covering the sinus on the side of the face, and with a scalpel make a transverse incision over the sinus. In one case (says Sir B.) I did otherwise, thinking the division of the membrane, not a separate part of the operation, was unnecessary; but the consequence was, that the blood escaped into the cellular membrane underneath, and there was an immense ecchymosis, producing the rest of the operation very difficult. Then perforate the thick plate of bone as nearly as possible to what you suppose to have been the original seat of the disease." The best instrument for this purpose, according to Sir Benjamin Brodie, is a pair of sharp-pointed strong scissors. "Apply them to the bone in their closed state, using them as a shisel, and they will easily penetrate it, and go into the antrum. With these the bone may be easily broken down to the requisite extent." (See *Mé. de l'Acad. de Chir.*, t. vi., p. 35; *Graaf's Diss. Append.*, p. 138.) Some surgeons, when it is absolutely necessary to expose a great part of the surface of the bone, and to cut away the dead species, which are wedged, as it were, in the living ones. In general, however, it is prudent to wait till the dead bone is loose, and in the mean while to restrict our interference to preventing the lodgment of matter, and rejecting any effluvia.

TUMORS IN THE ANTRUM.

Surgical writers describe polypus of the antrum; and as growths of this kind have their origin from parts invested by mucous membranes, it is natural to expect that the antrum would occasionally be the situation of them. Yet this disease must be very rare; and Sir Benjamin Brodie even regards the history and treatment of polypus of the antrum as altogether hypothetical; and he adds, "No polypus, I believe, ever existed in the antrum external to the antrum

could join a ligature; and I never heard of the operation being performed." (See *Lond. Med. Gaz.*, for Dec., 1834, p. 438.) In an hospital, either civil or military, have I had an opportunity of seeing a polypus of the antrum; neither has any case presented itself to me out of an hospital. I join Sir Benjamin Brodie, therefore, in believing the disease to be exceedingly rare. There are, however, some good authorities in confirmation of the fact that polypus sometimes grows in the antrum. (See *Grav. Chelms. Diss.*) Certain other remarks, respecting whether the antrum, and the nasal cavity, some of which are of a fibrous, cartilaginous, or osseous, or cartilaginous character, free from malignancy, while the others are of a malignant character, participate of the nature of medullary tumours, or of sarcomas, and sometimes of both these formidable diseases together. Malignant tumours are attached to the antrum sometimes, and fill up the cavity. At first the patient has but little pain, and the existence of the disease is scarcely indicated by any particular symptoms. But, as the disease advances, things are different. The tumour, growing larger, presses upon the inferior part of the antrum, and causes the bony portion to become dilated. By degrees, it forms a projection in the cheek. After a time, there is another projection in the bony palate. Then another projection occurs at the inferior part of the orbit; and there is still another blocking up the nostril. Then the pressure of the tumour, the osseous portion of the antrum is absorbed; the alveoli are destroyed; and the teeth are loosened, or drop out. At length, the medullary growth, making its way up the orbit, displacing the eye, and then passes through the orbital plate of the frontal bone into the skull, and forces fatal, or else it penetrates through the front, or lower part of the antrum, in either of which last situations it presents a large fetid, bleeding mass, bringing the patient to his doom with rapid certainty. In the Museum of London University College are three specimens of malignant disease of the antrum: in two, the swelling made its way from the antrum to the brain; in the third, which was taken from an elderly woman, a patient of mine, who died in the North London Hospital, the medullary and osseous mass, after entering the orbit and displacing the eye, caused liberation and sloughing of the cheek, and a protrusion of scalp of the thumb in this direction. The woman, who had several indolent ulcers from the pressure of the tumour, as it continued to enlarge, was at length worn out by the discharge, irritation, and repeated bleedings from the disease. I remember a boy in St. Bartholomew's Hospital, many years ago, in whom a medullary tumour, beginning in the antrum, made its way through the orbital plate of the frontal bone and entering the plate of the ethmoid into the cranium. He was only counted about forty-eight hours before he died, though the portion of the swelling projecting into the cranium, and causing a corresponding depression in the integuments of the bone, was not in size to a small nutmeg.—C.]

This article under this head, I inadvertently omitted to record a new and difficult operation performed for the removal of a fungus from that cavity, by Dr. A. H. Stevens, Professor of Surgery in the University of New-York. The details of the case are included in Dr. Steiner's Appendix to Velpeau's Surgical Anatomy, recently published. It is the more important I

should introduce it here, since in another part of this work I have alluded to Dr. Rogers the more of having first operated in this country for the removal of the upper jaw. Dr. R.'s operation was performed, it will be perceived, in May, 1824, while that of Dr. Stevens was in August, 1823. I was led into this error, as respects the date, by the circumstance that the latter operation was not published until the present year, the author having withheld the report of the case from the public from a desire of delicacy to the patient and his friends, but the individual should be identified, and the extent of the mutilation shown.

The tumor in this case occupied the whole anterior aspect of a broad base from its lower portion, and occasioned a great deformity in the cheek, and protruded from the mouth.

For the full account of this singular operation, I must refer to the work just mentioned. It will be sufficient here to state, that a great portion of the anterior and inferior portions of the os maxillare superius were removed without dividing the cheek, by drawing up the commissure of the lips, and dissecting the upper lip from the bone to within a line of the infra-orbital foramen. And the portion of the operation is in the manner of raising the lip by a flexible elastic rod, made of iron-spring instead of the use of the nail, chain, and pegs, and the still more painful and equivocal operation with the actual cautery.

This patient is now living in perfect health, and the cavity in the cheek which followed the operation has been filled by an artificial jaw, made of ivory, having teeth attached to it, and the articulation and deglutition are so perfectly restored, that only a few friends are aware of the nature of the operation to which he has submitted.

This entire though of not so severe a form of a disease is alike honorable to Dr. Stevens and the profession.

Professor Chapin A. Harris, of Baltimore, has reported in the *Maryland Med. and Surg. Journ.* for 1840, a highly interesting case of cancer, to which I must refer the reader, as of great practical importance. It was cured by the extraction of the first superior molar tooth, the roots of which were found greatly enlarged by cancerous action. This operation was found to have opened the system, and allowed the escape of a purulent and foetid discharge, and indicating the proper treatment, as well as revealing the true source of the patient's suffering. The patient was thus restored to health after being tortured by scrophulous for years.

Dr. Warren, of Boston, has reported in the *Boston Med. and Surg. Journ.* for 1839, a case of fungus of the gumma, of so great extent that the nasal cavity, and what were supposed to be the common cavity by the destruction of the bony structures, and which required the removal of the upper jaw, signified the miller bone. The patient, speedily relieved thus, had a complete mutilation, so desirable to the surgeon who thus rescued him from a horrible death. See Dr. Warren's work on Tumors, and Impetigo Jephson.—Rohrk.

[ANUS.—PROLAPSE AND]

In the treatment of a child, Sir Benjamin Brodie recommends occasional purging with calomel and rhubarb; the prohibition of such vegetable food, which tends to fill up the intestines,

while it affords but little nourishment; and an injection, every morning, of two or three ounces of a lotion composed of ʒi of ether, four ounces of water, and a pint of wine. The child is to retain the injection as long as possible. Sir Benjamin Brodie has never seen a prolapsus of the rectum in a child which was not cured in this manner.

ARTIFICIAL ANUS.

The following general directions were given by Dupuytren for the application of his *Artificial anus*.—1. The two ends of the bowel must be exposed. 2. The septum between them divided. 3. The external opening fixed up.

The lower end of the intestine he frequently found very difficult to make out. In old cases, very often, neither the sigmoid flexure nor the lower portion of the bowel could be discovered; and it seems as if there was only one passage leading to the rectum. The other, particularly in new and enlarged within the belly, has in general so concealed, that, unless accidentally aided by a probe, its detection is almost impossible. Then the relation of the two portions of intestine to one another Dupuytren found remarkably constant. The stenotic point, according to the kind of case, may be superior or inferior, external or internal. When the superior was especially enlarged was the great obstacle, he sometimes found among the best means of discovering the orifice of the lower continuation of the intestinal canal. In very difficult cases, he sometimes the use of a plug, purgative clysters, and a very small diet. (See *Cancer Glor.*, t. 2, p. 265.)

The two ends of the bowel being exposed, the operation must not be performed if the enormous cost of the bowels, the peritonitis, or other organs be the seat of acute or chronic inflammation. The patient is to be prepared by a suitable, mild, antispasmodic plan.

In the operation the patient is to lie upon his back.—The surgeon takes one of the branches of the extensor in the right hand, and pushes it, if requisite, with the left forefinger to one of the orifices of the bowel to the depth of two, two, three, or four inches, according to circumstances. An assistant then takes charge of this first part of the instrument. The other branch is then introduced into the other end of the bowel in the same manner.—Both branches are then brought together, and joined like a pair of dividers. The blades are then made to grasp the bowel by pressing the handles together. The pressure is next regulated and maintained by means of a screw. Before the expiration of the first day the pressure is to be increased sufficiently to kill the portion of intestinal tube embraced by the instrument, and the pressure is to be continued every second day to render these dimensions still more certain. In the cases under Dupuytren, the instrument was detached between the seventh and tenth day, being removed with it the distending padding sponge and septum, which prevented the upper portion of bowel from communicating with the lower. Frequently the first signs of the re-establishment of the natural process precede the detachment of the instrument. In all cases slight recte occurs, the evacuations are at first white and slimy from the lower bowels, and these are followed by stercoraceous matter from the upper ones. As long as the contents are liquid, and mixed with mucus, and they soon become of better quality, and all unpleasant sensations. (See *Dupuytren in Clin. Chir.*, t. 2, p. 294, 295.)

FISTULA OF THE ANUS.

As they are termed, consist of large superficial ulcerations near the anus, between the converging folds of the true skin and mucous membrane. When the folds of the anus are separated, and the fistula is deemed to straddle, a narrow fissure is seen, the bottom of which is red, and the margins somewhat swollen and callous. But in Dupuytren's observation, it is frequently necessary for the purpose of ascertaining how high it reaches, to introduce the finger into the rectum. It is much more highly situated at the sides and back of the anus, than at the forepart of it; a favourable circumstance is relative to its operation, particularly in women, in which the opening is divided from the posterior column of the vessel only by a thin partition. The inflammation chiefly affects the whole thickness of the mucous membrane. (See *Dupuytren, Clinique Chir.* t. ii., p. 223.) Fissures of the anus are usually productive of violent lancinating or burning pain, which gradually augments, and lasts a considerable time after the patient has had a motion. In some cases, indeed, so extensive is the suffering, that the patient feels a dread of obeying the call of nature, so long as possible, or even usually starts himself, to render the operation for emptying the rectum less frequent. The severity of the case arises chiefly from a painful spasm of the sphincter muscles.

Constipation, and the spasm which it excites, are among the predisposing causes of fissure of the anus. The indurated fecal matter, either by raising ulceration of the mucous membrane, or by immoderate distension of the passage, may bring on the complaint. The unskilful administration of clysters, especially with pointed rough tubes, is often the cause. Persons of the anus are frequently met with in persons who have piles; and, according to Dupuytren, the lodgment of viscid matter near the anus, as happens in many women, may lead to the complaint. Perhaps it would be more correct to say that the contact of any irritating matter of secretion may give rise to it.

According to Dupuytren, the spasmodic constriction of the sphincter is the real disease, and the fissure is only a secondary effect. By putting a stop to this constriction the disease is cured. With this view, Dupuytren tried what good could be done by the following operation: R. *Aloësis* ʒss., *extr. belladonnæ plantif. rectif.* ʒss. Mac. A pint of limon-champagne, or as I should say, a soft rectum bougie, of moderate size, smeared with this ointment, is introduced, and the diameter gradually increased to that of the forefinger. Dupuytren states that the continuance of this treatment for a few days frequently cures the pain entirely, and dissolves all tendency either for cicatrix or the division of the sphincter. Even when the plan does not cure, it always palliates, and therefore should be tried before the latter method is resorted to.

Bacon Dupuytren makes a very useful and practical division of fissures of the anal into three kinds. *First* are those the sphincter, affecting hardly any thickness of the skin, and not the mucous membrane. These excite more or less pain, but cause little obstruction to the passage of the feces. *Second* are the sphincter, involving the mucous membrane, and only to be seen with the aid of a speculum. When the finger is passed into the rectum, a knotty hard chord is felt, and pressure well creates acute pain. When

the patient goes to stool, such fissures give rise to an intolerable sort of stinging, which ceases directly after the evacuation; and the expansion of the soft segment the fissure is covered with puriform or mucous, bloody fluid. Such fissures were found by Dupuytren to be essentially produced by the distension of internal piles, excited by the passage of indurated fecal matter. Lastly, fissures of a *third* kind, *third* are, not the worst, being attended with agonizing constriction of the sphincter, and other symptoms already specified.

The first two descriptions of fissure may often be cured without any operation; some by the fissure itself with simple means, of constant exfoliating action, mucous preparations, for others by emollient anodyne lotions or applications. But when the fissure was of the third description, Dupuytren considered the operation first introduced by Borel the quickest and most certain mode of cure. This consists in dividing the anus and sphincter with a probe-pointed bistoury, passed into the rectum, and cutting directly through the fissure, except when it lies forward towards the vagina in the female, or hymen in the male subject. When several fissures existed, Dupuytren sometimes made several cuts in different directions, from those to five lines deep. (See *Clin. Élec.* t. ii., p. 10.)

PRETERNATURAL CONTRACTION OF THE SPHINCTER.

Sir Benjamin Brodie has treated of this as a distinct affection, and, indeed, we find that Dupuytren represents it as being generally the primary complaint in fissure of the anus. The cases referred to by the former gentleman he has met with chiefly in women disposed to hysteria, though sometimes in the male sex. In emptying the rectum, the patient is obliged to strain very much, especially when the feces are solid; then pain is experienced, which lasts a considerable time afterward. Very often a small ulcer of the mucous membrane of the rectum (the second variety of Dupuytren's fissure) accompanies spasmodic contraction of the sphincter, and is always, according to Sir Benjamin Brodie's description, situated at the posterior part, opposite the point of the os coccygis. When the suffering is not excessive, relief may sometimes be derived from purgatives, given to prevent the evacuations from being hard and dried, from an opiate suppository at night, and from the introduction of a bougie into the anus just before the patient has a motion. In worse cases, Sir Benjamin Brodie recommends the division of the sphincter with a straight probe-pointed bistoury. The *first* of the vessels are thick, and will require two or three strokes for their complete division. An anæsthetic may be given to keep the bowels quiet for two or three days afterward, with a diet of water or may be exhibited. Simple dressing will suffice to heal the wound. (See *British Med. Gaz.* for 1833, 1835, p. 36.)

EXCERIMENTS OF THE ANUS.

These cases are frequent, the growths resembling a variety of names, according to their supposed resemblance to things, as condylomata, excoriations and &c. Some are much firmer than others; some of them grow in consequence of irritation of the skin of the anus, by the contact of rural secretions or putrid matter. Others are originally piles, for, as Sir Benjamin Brodie observes, often the ravages of external piles be-

cornea obliterated, their generally firm flaps of skin, which gradually waste; but sometimes diseased action takes place in them, so that they become converted into excrescences similar to those which grow from the nymphs of women. Many observers share the mistaken perception of a middle existence, between that of a wart and that of a polypus. I have observed great number by stimulating applications, as the nitrate of silver, the zinc sulphate, the acetic acid, and the powder of yarrow, blended with carbonate of copper, or a solution of the sulphate of copper. When their tegula have been removed, I have also extirpated many of them with large forceps. But, in general, I remove the larger kinds with a bistoury. The bleeding, which may be at first copious, does not generally require a ligature, as it stops as soon as wet or linen dipped in cold water, and a T bandage has been applied. (See *Fluorazentis and Barytes*, p. 45.)

[Dr. J. C. Warren, of Boston, has cured twelve cases of fungus of the eye. In three of them he resorted upon exclusive medicines and the local application of the nitric acid; but in nine of them he found it necessary to divide the sphincter with the knife.]

The late Dr. George Swale, of New-York, published in 1847 a treatise on the malformations, injuries, and diseases of the rectum and anus, which will be found to possess very great practical value. It is composed in some three hundred octavo pages, and accompanied by nine quarto plates.

In Professor Gibson's late work on the Institutions and Practice of Surgery, vol. ii., p. 140, a just encomium will be found upon Dr. Physick, of Philadelphia, for his ingenuity and successful operating for artificial anus formed by him in 1808, and afterward imitated, with similar success, by Dupuytren of Paris. The claim of Dr. Physick to priority in this surgical achievement is fully sustained by Dr. Gibson, by an extract from Dr. B. H. Coates's able paper on the subject, published in the *N. A. Med. and Surg. Jour.*, vol. ii., p. 360.

Dr. J. R. Letz, of New-Berlin, Pa., has successfully operated by a method which he considers an improvement on both Physick and Dupuytren. (See *Amer. Journal*, No. 38, p. 367.)—*Review.*

[AORTA: COMPRESSION OF THE AORTA.]

In order to restrain hemorrhage from the anterior half of the body, more especially from the uterus, has been warmly advocated, and in this purpose seems calculated to be beneficial. (See *Grover, Provincial Med. and Surg. Trans.*, vol. 5.) I have mentioned the adoption of this plan by Sir Astley Cooper, in the case where he operated the aneurism, and previously to putting a ligature on the aorta.—C.]

[ARSENIC. Dupuytren was in the habit of employing certain preparations of arsenic, which claimed the diseased surfaces without destroying them. One of his formulae was a powder, the other a liquid. The arsenious acid constituted the basis of both. The calomel, joined with it, he conceived might have some effect, but the arsenic was the essential thing. The powder consisted of two parts of arsenious acid and one of calomel, and thirty-six of calomel. Something the proportion of arsenic was increased to five or six parts in the hundred. The liquid preparation was principally the above powder mixed with gum arabic, and sweetened with distilled water,

so as to make a paste. In the latter formula, however, Dupuytren usually increased the proportion of arsenic, employing six, eight, ten, or twelve parts of arsenic with an equal part of calomel, as made, with the arsenic, one hundred. Dupuytren employed this application with considerable success for the cure of many phagedenic ulcerations of the lips, and other parts of the face, approaching almost to cancer in respect to duration. (See *Chirurg. Cas.*, t. iv., p. 471.) In the North London Hospital I employed Dupuytren's arsenical powder last year, in one or two instances of the same kind, with complete success. In leprosy, or cutaneous cancer, it is a valuable application.

If the pump be used, Dr. A. T. Thomson is of opinion that lime-water should be used to wash out the stomach. The union of this and arsenious acid forms a nearly insoluble salt, so that, while we are treating the stomach with arsenious extract, we are also lessening the risk, in case of any part of it which may remain. If the above remedies be given, lime-water should be drunk immediately after the last dose of arsenic. Oil, and also milk, may be given, but no strong fluid calculated to dilute and remove the arsenious acid. Alkaline solution are absolutely contraindicated, the alkaline acetates are very active, and as potash, are as caustic as lime. (See Thomson's *Elements of Therapeutics and Materia Med.*, p. 518, ed. 2.)

In 1838, the peroxide or bromised starch of iron was discovered by Dr. Bence to be a general antidote if administered in time. (See *J. of Chem. in Pract. Med. Trans.*, vol. 3, part 2, *J. Review in Lond. Med. Gaz.*, Nov. 5, 1838.)—C.]

[ARTERIES. In the article Aneurism I noticed the questions about the propriety and safety of tying both carotids, and whether this could be done without extraordinary risk when no interval was left between the two operations. With respect to these points, I find that M. Harter is decidedly of opinion, that both the common carotid arteries may be tied at once in the same individual, without any marked or lasting derangement in the functions of distant parts of the head. He believes that the numerous anastomoses which exist in the interior of the skull between the terminating branches of the vertebral arteries and those of the internal carotid, are more than sufficient for the easy conveyance of blood from the former into the latter, and for the prevention of the brain from being sensibly affected by the obliquity of the two common carotids. Externally, the numerous communications between the branches of the external carotids and those of the two subclavian arteries, more particularly the free anastomosis of the lower thyroid with the superior thyroid arteries, and those of the ascending cervical with the occipital arteries, have no doubt in M. Harter's mind respecting the correctness of the opinion which he has advanced. He has frequently tied both the common carotids in animals without the slightest impairment of their intelligence or of their general health. At the period when he was recording his views of the subject, there was in the dissecting-room of the hospital a large, strong, healthy dog, on which he had performed this operation five years previously, and whose intelligence continued perfectly undiminished. So far continued in M. Harter's view of the safety with which it may now be practised on the human subject, that he wished to undertake it on a younger man who had an an-

lympe tumour of erectile union on the feet, but who would not submit to the proposal. (See *Masses, Trunks, &c. de la Lig. des Arteries*, p. 18.)

Perhaps, in an operation of tying an artery, is the exclusion of the vein and nerves of so much consequence as it is in that of applying a ligature to the common carotid artery. As I frequently remark, this fact depends upon the importance of the organs to which the adjacent nerves are distributed, viz., the heart, lungs, and stomach. (See *Lectures Quinze*, &c., t. iv., p. 17.)

The right common carotid trunk is much shorter than the left: the former arising from the tracheocephalic trunk, the latter from the subclavian artery. Both trunks approximate the space between the scapulae and upper edge of the thyroid cartilage; and behind each of these are the jugular vein and vagus nerve, with the subclavian vessels, placed in front of the common carotid. In the lower part of the neck, the trunks are placed three inches higher up, the thyroid gland, and still higher up, the larynx and glottis. The external side of the common carotid is in contact with the internal jugular vein, which partly overlaps it; while between the two vessels, but rather behind them, and enclosed in the same common sheath with them, the pneumogastric nerve is visible. As the lower part of the neck, the carotid sheath has behind it the recurrent laryngeal nerve, and the inferior thyroid artery. The descending branch of the ninth nerve, commonly low above the thyroid gland, closely connected to it, and about the middle of the neck forms a plexus with several filaments from the second and third cervical nerves. At the upper part of the neck it lies rather towards the outer side of the sheath: at the lower, on the inner side of it. Mr. Harrison has often found it within the sheath, behind the jugular vein. The sympathetic and vagus nerves are situated between the sheath and the pneumogastric nerve. The common carotid artery is covered below by the skin, platysma, and dermal fascia, and also by the sternomastoid, sterno-hyoid, and sterno-thyroid muscles. Opposite the upper rim of the trachea it is crossed by the omohyoides, but from this point to its termination the vessel is covered only by the skin, platysma, and fascia. The omohyoides, as it proceeds from the shoulder, behind the sterno-mastoid muscle, divides the artery into an upper and lower portion, and the side of the neck into two triangular spaces. In the lower triangle, bounded by the trachea, clavicle, and omohyoides itself, the common carotid is concealed by the sternal origin of the mastoid muscle, and lies deeply; but in the upper triangle, bounded externally by the margin of the sterno-mastoid muscle, above by a transverse line, denoting the uppermost extent of this space below the scapulae, and below by the omohyoides, the vessel is much more superficial. Here, however, a plexus of veins often has its setting in view of the common sheath. (See *Vid. p. 18.*) *Masses, Trunks, &c. de la Lig. des Arteries*, No. 1, pl. iv.) A chain of abscesses starts in near the carotid sheath, principally on its external side, and are partly concealed by the sterno-mastoid muscle, and covered by the cervical fascia. In young subjects they are large and numerous; "they are frequently enlarged and indurated by chronic inflammation, the muscles and fascia press them

closely to the vessels; they become fixed, and have a pulsation communicated to them, so as to resemble aneurism." (*Masses, Trunks, &c. de la Lig. des Arteries*, p. 23.)

The operation of tying the common carotid is sometimes performed while the patient is in the sitting posture; but, on account of the chance of his becoming faint, I consider the recumbent position best, with the chest somewhat raised, the neck moderately extended, and the chin turned towards the opposite side. If the artery is to be tied below the omohyoides, the front edge of the sterno-mastoid muscle is to be first felt for, and an incision, three inches long, made in the direction of it, commencing opposite the cervical cartilage, and directed towards the sterno-clavicular articulation a little above which it is to terminate. On the other hand, when the artery is to be taken up above the omohyoides, the incision through the skin should begin higher up, and not be continued so low down. The second stroke of the knife divides the platysma myoides and dermal fascia, so as to bring into view the fibres of the sterno-mastoid muscle. Unless the latter muscle be made over the latter muscle, it is best to punch up a portion of the cervical fascia with the forceps, and cut it across, so as to make a small opening in it for the introduction of a director, on which it is to be slit up. (See *Quinze de Chirurgie*, p. 439, ed. 2.) An assistant now draws the lower margin of the wound, and the sterno-thyroid and sterno-hyoid muscles, towards the median line, while the surgeon himself divides the external margin of the wound, and the sterno-mastoid muscle external. For this purpose, bistouris are sometimes preferred, as not cancelling the parts so much as the finger.

The omohyoides is now seen running across the normal in the form of a red cord, and above and below it are the vein and artery, enclosed in their common sheath.

The sheath should be opened over the artery, and not over the vein, with the aid of a pair of forceps and a director. If the jugular vein swell up so much as to conceal the parts, pressure is to be made on it at the upper angle of the wound. (See *Vid. p. 18.*) *Masses, Trunks, &c. de la Lig. des Arteries*, No. 1, pl. iv., p. 241.) Then an eye-needle, or aneurism needle is to be conveyed between the vein and artery, and under the posterior surface of the latter, without meddling with the pneumogastric nerve, the great sympathetic, or any of their branches.

It seems to M. Volp, that if the surgeon were to cut at first to the inner side of the mastoid muscle, there would be some risk of meddlesome the sterno-hyoides for it not getting wrong. He thinks it better, therefore, to slit down upon the surface of the sterno-mastoid muscle, a few lines from its anterior margin. As the cords of the vein are very thin and easily torn, the knife is never to be applied near it.

If the sheath were not duly opened, the pneumogastric nerve, situated within its posterior layer, between the carotid and jugular vein, would certainly be tied, and the carotid nerve and descending may be in danger of being tied the same time.

The ligature of the common carotid above the omohyoides is rendered easier by the more superficial situation of the vessel, which is merely covered by the skin, platysma, and the cervical fascia. The incision is to commence a little below the angle of the jaw, and be continued down in the extent of about three inches in the upper triangle of the neck; that is, in the triangular

between the stylo-mastoid muscle and the larynx. The skin and platysma having been divided, the cervical fascia is to be pushed up with a pair of forceps, and an opening made in it by cutting it across. Then a director is to be introduced, and the operation finished according to the directions already given as applicable to that below the omohyoides.

In the operation of splitting a ligature to the subclavian artery, in the axilla of the axillary artery, the patient is to lie on his back, with his shoulders somewhat raised. The head and neck are to be turned towards the external side, while an assistant depresses the shoulder, and raises the arm from the side. The first incision is to be made transversely, an inch above the clavicle, at Volkmann's point, or near, or even upon, its very outer surface, prefer, from the outer edge of the stylo-mastoid muscle to the front edge of the trapezius. After the integuments have been cut, the platysma myoides is to be divided. The external jugular vein itself may generally be drawn aside with a blunt hook; but, if this cannot be readily done, a double ligature must be put under the vein, and tied, after which it is to be cut through in the interspace. Then the cervical fascia is well exposed, which is to be carefully opened by picking a piece of it up with the forceps, and making a small opening, which is to be enlarged with the end of a director. The edge of the scapular artery can then be immediately felt under and within the stylo-mastoid muscle. After having incised or separated the cellular tissue, adipose, plexus, &c., to the bottom of the wound, with a probe or a director, the finger is conveyed towards the insertion of the scalenus, where the intercostal of the first rib will be felt a little behind and on the outside of which the artery is always situated.

When once the artery is found, it is not necessary to bring it into view: for the nail, being applied to its posterior and external side, serves as a guide for the best exposure or dissection made, the point of which is to be passed from before backward, and a little from without inward, the surgeon keeping his finger over the artery, between it and the lowestmost nerve of the brachial plexus, so as to steady the vessel. (See Volkmann, *Not. Edin.*, &c., t. 1, p. 224.)

With reference to the ligature of the external iliac artery, I have but little to add to the account given of this vessel in the article *Arteries*. From the retro-iliac symphysis, where the common iliac artery bifurcates, down to the femoral arch, the external iliac artery describes a gentle curve, which is more marked in the female than the male subject, and the convexity of which is turned outward and backward. The artery descends along the inner margin of the psoas major, etc., to which it is connected by a thin membrane, derived from the gluteal fascia, stretched behind the artery. Although the probability from the iliac fascia is so thin that the artery and vein can be seen through it, yet it is sufficiently strong to prevent them from being displaced or separated. (See Harrison's *Surgical Anatomy of the Arteries*, vol. 2, p. 117.) The vein lies in the inner side of the artery, and at first rather behind it; but, near Poupart's ligament, it is on the same plane as the artery, resting upon the psoas, and upon a few fibres of the psoas and pectineus muscles. The anterior crural nerve runs in the iliac side of the artery, but on a plane posterior to it, and separated from it by the psoas, between which and

the iliacus internus the nerve covered by the iliac fascia is imbedded. "Two or three small branches from this nerve, and from the lumbar plexus, are connected to the artery, and descend along its external side." These branches are distributed to the spermatic cord and to the inguinal parts of the groin." (See Harrison, *Op. cit.*) The vessel, in its descent behind the psoas, crosses over the anterior surface of the external iliac artery, and supplies the vas deferens. As for the peritoneum, it is connected to the external iliac artery mostly by loose cellular tissue, and below runs the vessel, which is to be reflected over the posterior surface of the capsule of the bladder. The only branches it possesses, which the external iliac artery gives off are the circumflex iliac and the epigastric, which issue in opposite directions from the same point, a quarter or half an inch above or below this point. The abdominal aorta, which is on the right of the external iliac artery, being sometimes enlarged, forms a sigmoid flexure, which does not exist. On the right side, the cœcum, and on the left, the sigmoid flexure of the colon, are the only vessels exposed between the external iliac artery and the umbilicus of the abdomen. At MM. Brocq and Volkmann's notice, nothing is easier, in a thin person whose abdominal muscles are relaxed, than to make it feel a pulsation in this artery. "At Volkmann's observation in a young man, who met with an accidental wound of the artery above the union of the external, requiring the vessel to be tied without delay." (See Volkmann, *Not. Edin.*, &c., t. 1, p. 172.)

In Abernethy's method of tying the external iliac artery, an incision is made, about three inches and a half in length, in the direction of the artery, down to Poupart's ligament. The symphysis of the external oblique muscle being thus exposed, is to have an opening carefully made in it, and a director being now introduced, the aperture is enlarged in the direction, and to the same extent, as the vessel is the artery. "The internal oblique and transverse muscles, which are closely connected with each other, are to be carefully cut into the lower part, so as to allow a director, or the point of a hook, to be introduced below them, where they also are to be divided, the finger separating them from the fascia transversalis and peritoneum. The fascia transversalis, running from Poupart's ligament to the pubis, is perforated through with the nail, immediately over the pulsating artery, and the peritoneum is to be separated by the finger, and pushed upward and outward, so as to be detached, which, in this, as well as at all other operations on the iliac artery, is sometimes difficult, on account of the protrusion of the intestines, caused by the peritoneum, when the patient is not sufficiently aspirated. The artery is put at some depth, and covered by a thin cellular membrane, connecting it to the vein on its inside, and which must be torn through with the nail. The membrane itself is to be moved between the vein and the artery, and the point made to appear on the outside of the artery." (See *Fluency in Dis.*, &c., of the Arteries, p. 172.) This description, with the observations in the article *Arteries*, will suffice of nearly Abernethy's plan very intelligible.

To the account of the Artery Clavicular, we add of taking up the external iliac artery, given in that part of the Dictionary, *Arteries*, &c., &c.

In the article *Anastomosis*, a description is given of the operation of tying the *femoral artery* in the upper third of its course. If it were indispensable to apply a ligature to it in the groin, or just below the crural arch, the surgeon should remember that here the situation of the artery corresponds to the mid space between the superior epicondylar process of the humerus and the inferiority of the os pubis; though, in women, in whom the pelvis is wider, this artery is rather nearer the pubis. The vessel may also be readily felt as it is passing over the os pubis, being only covered by the integuments, superficial fascia, some lymphatic glands, and the fascia lata immediately below Poirson's ligament, the femoral vein, less on the pubic side of the artery. The anterior epical nerve branches half an inch away from the iliac side of the artery, imbricated between the claud and pectus muscles. (See *Harrison's Surg. Syst.*, 3rd. ed. ii. p. 136.) After the operation is completely done on one side of the artery, not interfering in any way with its distention, not striving as a direct guide for it, as it lies in the middle third of the thigh. In the operation, the limb should be extended and rotated inward, as directed under, beginning about an inch above Poirson's ligament, and extended downwards, in the direction of the artery, in the distance of two-thirds before this ligament. The layers of the superficial fascia are then to be divided to the same extent, making lymphatic glands in the way, pushed to one side, or, if enlarged and diseased, removed. The fascia lata is next to be divided, and the sheath of the femoral vessels pushed up with a pair of forceps, and cautiously opened. Lastly, the anastomosis, or syringe used for the conveyance of the ligature under the artery, is to be introduced on the pubic side of this vessel, between it and the vein, so as to have the latter completely cut. As, in some individuals, the origin of the profunda is unusually high up, and of nearly the same size as the femoral, one of them might be mistaken for the other. The profunda, however, is the more external of the two. The effect of pressure is such in checking the hemorrhage, in the pulsation of an anastomosis, will also be a guide to the operator. (See *Harrison, Op.*, vol. iii. p. 160.) Sometimes a double femoral artery has been met with.

The direction given by N. Meisner, to place the ligature as closely as possible above the origin of the profunda (*Mon. & Med. Op.*, 7. 185), if adopted, would be very likely to be followed by profuse hemorrhage, for vessels elsewhere exposed. (See *Harrison, Op.*)

The operation of tying the *femoral artery* in the middle third of its thigh has never been fully described in the article *Anastomosis*, I attach the following particulars. This artery, in its course from the epical arch to the lower third of the thigh, runs in the direction of a line, which, drawn from the centre of Poirson's ligament, descends obliquely inward toward the line to the middle of the popliteal space. This direction is nearly correct; but, as Dr. Quain observes, as this line runs along the inner border of the thigh, its course is more oblique than that of the vessel, which is placed much nearer the axis of the femur. (See *Ann. of Anat.*, vol. ii. p. 2.) In the middle third of the thigh the femoral artery is more deeply placed than in the upper, because, in addition to the integuments, superficial fascia, and fascia lata, it has the sartorius lying over it, beneath which there is also another fascia, ex-

posed over it, from the adductor muscle to the vastus internus. This fascia, though thin, is very dense where the artery approaches the opening in the adductor magnus. In the groin the femoral vein lies close to the inner side of the artery, but as it descends it gets more under the latter vessel, behind the popliteal space it is situated quite to the outer side of it.

An incision three inches in length is to be made along the inner edge of the sartorius, which is the common rule, and perhaps better than Liston's modification, which consists in making an incision of this length in the mid space between the gracilis and sartorius; for, by exposing the fibres of the latter muscle, there is more efficient manual instruction to the surgeon. For he then knows immediately where he is, and what ought to be done. The integuments and superficial fascia having been divided, and the fascia lata to the same extent, the inner edge of the sartorius is exposed. This is to be gently raised and drawn outward. The fascia, extending from the vastus internus to the adductor, and covering the artery, is brought into view, and, with the aid of a pair of forceps and a scissor, it is to be externally opened, by which means the sheath of the femoral vessels will be exposed from the great epical arch down within the sheath, on the internal and external side of the artery, and the vein is not to be incised in the ligature. Lastly, the anastomosis needle is to be conveyed under the artery, between it and the vein. In making the incision through the integuments, the great epical vein should be avoided by not directing the knife too obliquely downward and backward.

In addition to what has been stated in the article *Anastomosis* respecting the *ligature of the brachial artery*, I may observe, that the course of this vessel corresponds to an oblique line drawn from the acromion to the middle of the bend of the elbow. The median nerve, which runs along its radial margin, soon gets in front of it, and, crossing it very obliquely, passes quite to its inner side below. Two satellite veins usually accompany the artery, and even sometimes cover it, and thus separate it from the median nerve. The ulnar and internal cutaneous nerves, which lie near it above, separate further and further from it as they descend, in order to reach the inner part of the forearm. The artery, lying at first near the humerus, between the coraco-brachial and the tendon of the latissimus dorsi, afterward passes over the insertion of the coracobrachialis, and gets upon the brachialis anticus, a little behind the inner margin of the biceps, which last imposes it altogether to its termination. In the upper third of the hand the brachial artery is less covered by the biceps; and hence, in the operation of taking it up, this position is advantageous. (See *Mon. & Med. Op.*, p. 186.) In this respect the brachial is almost analogous to it, and tends of a supracarpal to behind the artery, the two accompanying veins and the median nerve, all which form, as a vein, one common fasciculus.

The whole is covered by the common integuments, and, in the lower third of the arm, by the biceps of the brachial vein. The anastomosis of the brachial artery are very frequent. Velpeau and most other anastomosis have seen it divide near the axilla, and at nearly every other point between this and the elbow. In the subject Velpeau found its bifurcation take place two inches above the insertion of the biceps, to form the ulnar

and posterior interosseous. In another, the latter was completely independent of both the ulnar and the radial. Sometimes the two trunks produced by the bifurcation lay down to the forearm parallel to one another; in other instances they cross once, or several times, and it is not uncommon to find one passing the facter as so to get immediately under the skin, while the other, which then gives off the radial and the interosseous, remains its ordinary situation. (See *Volsen's New Atlas de Méd. Op.*, t. i., p. 210.)

In the operation of placing it together on the brachial artery at the bend of the elbow, the surgeon should remember that the course of the vessel here corresponds to a line drawn obliquely inward and upward, from the pituita of the front of the elbow to the inner border of the biceps. Its course is also denoted by the median basilic vein, which passes under the skin almost in the same line as the artery. An incision, between two and three inches in length, is to be made through the skin on the inner side of this vein, which is to be carefully drawn out of the way. Then, with the aid of a director, the fascia, and the flexor profundus, given off from the tendon of the biceps, are to be divided, which having been accomplished, the artery will present itself, bounded on the right and left by its two veins, scabrous, the median nerve lying three or four lines from its upper border. To facilitate the passage of the quadrum needle or director under the artery, the elbow is to be a little bent, and the instrument passed from within outward under the vessel. (See *Mace's Op. cit.*, p. 188.) If the operation were performed somewhat higher, the surgeon must remember that two or three inches above the trochlea of the humerus the median nerve would begin to be in front of the artery.

In the upper part of the arm, the brachial artery lies at the inner border of the coraco-brachialis, and has the median nerve at first external to it, and then in front of it. Below the insertion of the coraco-brachialis, it is situated at the upper edge of the biceps. Four circumstances are enumerated as guides for the external ligament: 1. The inner edge of the coraco-brachialis above, and that of the biceps below. 2. A line drawn from the middle of the axilla to the middle of the bend of the elbow. 3. Placing the finger on the median nerve, and feeling on its upper side. (Lefevre.) 4. The pulsations of the artery. The knife is carried in the direction of the artery from above downwards in the right arm, and from below upward in the left, and an incision made in the integument about three inches long.

With the forefinger the surgeon next endeavours to feel the median nerve, which presents itself as a round very hard cord, and to distinguish the artery by its pulsations. He then divides, with the aid of a director, one after the other, the fascia, and the sheath given off by it to the median nerve; and breaking, with the end of a probe or director, the fibro-cellular coating of the vessels, separates the artery from the veins, and puts a ligature upon it. Except when anomalies occur, the operation is simple. M. Volsen has only twice seen the median nerve under the artery. In all ordinary cases it is the first cord met with behind the inner margin of the biceps. (See *Volsen's New Atlas de Méd. Op.*, t. i., p. 211.)

No serious or complicated accidents have made the slightest mistake of tying the median nerve

for the brachial artery; I adhere to the practice never to tighten the ligature until he has tried the effect of pressure on what he supposes to be the artery.

In order not to mistake the ulnar for the median nerve, and to be led off even for the artery where it will not pass, it is an excellent rule to proceed in the operation from the exterior to the posterior part of the arm. (See *Mace's Op. cit.*, p. 187.)

Ligature of the Radial Artery at the Elbow.—It is the thumb, be forcibly extended, the motion of the distal phalanx and long extensor will be made very prominent. In the depression between them, the pulsations of the radial artery can be felt. The thumb being drawn away from the forefinger, an incision an inch and a half in length is to be made in the direction of the flexor tendons, first through the skin, and then through the fascia. The artery is then to be separated from some veins and nerves, ligatured with a probe or director. (See *Mace's Op. cit.*, p. 183.)

After the radial artery leaves the forearm of the wrist, it may be taken up by making an incision on the outside for the insertion of the extensor pollicis, intermedia pollicis and the tendon of the extensor carpi radialis pollicis. Between these tendons, the artery lies very deep, and can it is the extreme branch of the ulnar spiral nerve. We find the artery going close to the scaph, between the os scaphoides and trapezium. (See *C. Bell's Op. Surgery*, vol. ii., p. 272.)

Ligature of the Radial Artery in the Lower Part of the Forearm.—Here the artery can readily be felt, being easily covered by the fascia and the skin. On each side of it two veins, but the radial nerve or considerably to the outer side of it, having passed under the oblique transverse ligament a little below the middle of the forearm. An incision two inches and a half long is to be made a little way from the radial margin of the flexor carpi radialis, between the skin and the superficial fascia. The fascia is to be opened, and the artery exposed from within outward, or from without inward, as the surgeon may choose, as it is a matter of indifference; the nerve being out of danger.

Ligature of the Radial Artery in the Upper Third of the Forearm.—Here the artery runs in the space which separates the supinator radialis from the pronator teres and palmaris longus, externally to the external border of the flexor carpi radialis, and of course to the humerus and the vein. It is always accompanied by two veins, and its radial nerve is its outside. It is completely surrounded by a sheath drawn from the middle of the bend of the elbow to the distal end of the styloid process of the radius and the tendon of the palmaris longus.

In the direction of this line, M. Roux makes an incision about two inches with a half an inch, penetrating a little below the skin. If the median vein is met with, it is pushed aside. The fascia is then cut up with a director, and the artery of the flexor supinator drawn outward, without dividing it. The artery having been seen in view, the stemomuscular is cut, and it is passed under it then without entering on account of the nerve. (See *Mace's Atlas de Méd. Op.*, p. 184.)

Ligature of the Ulnar Artery in the Wrist.—Here the artery passes on the radial side of the posterior bone, with the ulnar nerve as an outer sheath, and a vein on each side of it. In this place

an incision two inches long to be made through the skin, cellular tissue, and palmar aponeurosis, one after the other. The artery having been thus exposed, an exploring needle is to be passed under it from without towards.

Below the surface of the forearm the ulnar artery is superficial, and may easily be taken up by making an incision upon the radial side of the flexor carpi ulnaris, between the tendon of which muscle and that of the flexor profundus dissection the vessel is situated. The artery, however, will not be reached until a thin aponeurosis under the fascia of the forearm has been divided. The nerve is either more under the tendon of the flexor carpi ulnaris than the artery. When the ulnar artery comes from the brachial above the elbow, it passes, and runs above the fascia, and is easily taken up in any part of its course.

For bringing into view the ulnar artery at the upper end of the forearm, the situation and breadth of the flexor carpi ulnaris muscle must first be ascertained. An incision is then to be made from above downwards, beginning five inches below the inner condyle of the humerus, and following the course of the inner margin of the above muscle to the extent of two inches and a half. The fascia is then to be divided, and the flexor carpi ulnaris drawn a little away from the flexor cubiti. In this opening, rather within the margin of the latter muscle, the ulnar artery will be hit with the finger, extending the course over the flexor profundus. The ulnar nerve is situated on the ulnar side of the artery. Mr. Guthrie's opinions respecting the propriety of dividing the muscles which covered the upper third of the ulnar artery have been noticed in the beginning of the preceding article.

Course of the Anterior Tibial Artery on the Foot.—The anterior tibial artery becomes very superficial about six inches above the instep, from which point it descends between the tendon of the tibialis anterior and that of the tibiocrural of the foot. It passes with these tendons under the singular ligament, and rather nearer to the internal malleolus than the external; thence inclining upwards, it penetrates between the first and second metatarsal bones to the side of the foot, where it anastomoses with the external plantar artery. The first branch of the deep dorsal nerve of the foot is at its entrance, its corresponding vein at its outer side. It is covered, 1st, by a thin fibro-cellular expansion, separating it from the adjoining tendons. 2dly, by adipose cellular tissue. 3dly, by the fascia of the foot. 4thly, by the median intermetatarsal. On the instep, the first branch of the posterior tarsal artery divides into two upon the outer side of the artery: that of the extensor of the great toe goes to the edge of the shoe.

An incision two inches and a half long is made in the skin, in the direction of an oblique line from the middle of the instep to the first intermetatarsal space. The skin, adipose substance, and fascia are to be divided, the fibro-cellular expansion between the tendons of the first two toes opened, and the artery laid, after being separated by means of a director from the accompanying veins and nerves. (Vide supra.)

Course of the Anterior Tibial Artery in the Leg.—The two upper thirds of this artery lie close to the interosseous ligament, but lower down the external edges towards the outer side of the spine of the fibula, respectively, the higher is on the more deeply it is situated. The two veins accompanying it fluctuate across it by

several small branches. The anterior tibial artery crosses over it obliquely upwards and downwards, though sometimes it continues on its outer side down to the instep. The artery, veins, and nerve are included in cellular tissue, which does not, however, form a true sheath for them. Above, the artery lies between the tibialis anterior and the interosseous cutaneous, in the middle of the leg, between the tibia and fibula and the extensor of the great toe, and still lower down, between the extensor of the great toe and the extensor communis.

In order to lay bare the anterior tibial artery a little above the middle of the leg, the finger is to be passed along the outer side of the spine of the tibia, and the breadth of the tibia anterior muscle is to be ascertained. Making the outer margin of this muscle an incision is to be made, through the interosseous and fascia, two inches and a half in length. The artery is then to be introduced between the outer margin of the tibia anterior muscle and the extensive ledge of the great toe. In this space, at the depth of about an inch, the anterior tibial artery is situated. (See Hall's *Less. Anat. Yench.* tab. 4; also *J. P. Moore, de la Lig. de l'Art. Ant.* p. 12.)

Course of the Anterior Tibial Artery in the Lower Tibia.—The skin, the interosseous lig., the cellular tissue, and the fascia, are to be divided in succession to the extent of about three inches, and in the direction of a line drawn from the heel point between the head of the tibia and spine of the fibula to the instep. Then, with a director or the forefinger, the tendon of the extensor muscle of the great toe is to be separated from that of the tibia anterior, passing it subwound from the extensor communis if the operation is at the upper part of the lower third of the leg, but instead if the operation be done quite at the inferior extremity of the leg. Nothing then remains to be done but to separate the artery from its accompanying veins and from the anterior tibial nerve, which in this part of the limb is at its inner side, having crossed it from the outer to its descent. (See Moore, p. 12, fig. 1; *Vid. supra, Nerv. Edm.* 4c, 6, 7.)

Course of the Anterior Tibial Artery in the Middle or Two Upper Thirds.—Laffaye makes an incision extending obliquely from below upwards, from the spine of the tibia towards the fibula. Having cut impudently through the fascia, the interspace between the tibia and fibula and the cutaneous is brought for.

In the ordinary method of dissection made in the first of this artery, as determined by the line above specified, about an inch on the outside of the spine of the tibia. The skin and fascia are divided to the extent of three inches. The muscular interspace, at the bottom of which the artery will be found close to the interosseous ligament, is denoted by a yellowish line. In order to observe the ligament round the artery, Velpeau passes a director under it very obliquely, from below forward, and from the fibula towards the tibia.

Course of the Posterior Tibial Artery.—From downward, a little before the popliteal muscle, in its division into the external and internal plantar arteries, the posterior tibial artery follows very precisely the direction of a line with a slight curvature, from the middle of the upper part of the calf to a point half an inch behind the internal malleolus. Two veins usually accompanying it anastomose forming by their structure a complete network round it. In the upper part

of the leg the posterior tibial artery lies to the inner or third side of the artery, but soon passes over it to the outer or fourth side. In the two upper thirds of the leg the posterior tibial artery is deep seated, lying in the upper third upon the tibia, posterior, in the middle third upon the flexor digitorum communis, while below down it is separated from the tibia only by latissimus pedis muscle. From the gastrocnemius and soleus it is united by the deep medial fascia, which muscles lie over its two upper thirds. In the lower third no muscles cover it.

In the arch of the os calcis the posterior tibial artery is in contact with the fibrous sheath of the flexor communis digitorum, about half an inch from the posterior border of the tibia malleolus. Here the artery is lodged in the sigmoid aneurysm. "The artery is encased in a pellicular and adipose tissue." The fibrous sheath of the tarsus, a fibrous layer continuous with the tarsus of the leg, after crossing the artery, becomes blended with the dense cellular tissue interspersed between the vessel and the skin. (See Velpeau.) Between the tarsal malleolus and the lower part of the calf, the posterior tibial artery is somewhat further from the lateral edge of the tibia, and the nerve is rather on its outer side than behind it. The degenerated fascia, which is here very thin, keeps the artery bowed down upon the tarsal malleolus, flexor digitorum communis profundus, and flexor digitorum profundus pollicis. External to this fascia is the course that the artery takes of the vessels of Achilles, and then the columnar form of the leg directly under the skin.

In the calf the posterior tibial artery is very deeply seated, almost on the same plane as the posterior surface of the tibia, and much nearer to medial than to lateral edge than its internal. It is covered by a strong fascia that lies over the flexor muscles, and then by the fibrous portion of the system; the internal head of this gastrocnemius; the fascia of the leg; the adipose cellular tissue, in which are found the great superficial vein and the internal saphenous nerve; and lastly, the skin. (See Velpeau.)

Course of the Posterior Tibial Artery.—The leg is to be bent and laid upon the outside.

Behind the malleolus internus.—An incision, slightly curved, with its convexity forward, is to commence at the malleolus, and to terminate an inch below the posterior edge of the malleolus internus, and to be at least three lines behind it. It will, therefore, be between the malleolus internus and the tendon of Achilles. If the operation is to be performed in the hollow of the os calcis, it is necessary, as M. Velpeau directs, to divide the tibial capsule, layer by layer, and to introduce a director under the fascia previously to its division, lest the artery, which is sometimes very superficial, be wounded. If the incision were made too near the malleolus, the firm support of the arch would be wanted. If too far behind, the artery would be more difficult to find. (See Velpeau, *New Evid. de Med. Quæ.*, t. 14. In fact, when the lower end of the tibia, the tendons of the flexor digitorum and of the flexor digitorum communis pass, in a kind of purse. Along with these two tendons, but somewhat nearer to the os calcis, the posterior tibial artery descends to the sole of the foot.

The depth of the posterior tibial artery at the two upper thirds of the leg makes it difficult to take it up in these situations. When necessary, however, it may be exposed, and tied above

and below the second is it, by proceeding as follows: An incision four inches in length is made along the inner side of the tibia; the cellular tissue is detached from the bone to the same extent, and reflected. The internal saphenous vein is to be avoided. Under the flexor digitorum communis, which is passing the muscles of the calf into superficial and deep-seated. When this fascia has been divided, the posterior tibial artery may be seen as well, deeply seated, resting on the tibia, posterior and lower middle of the vein. (See *Atlas*, *Ann. d'Anat.*, t. 1, pl. 5.; *Mémoires de la Soc. de Médecine*, 1822, pl. 13-4.)

The method of trying to tie up the posterior tibial artery, by making the incision at the lower end near the edge of the tibia, is thus proved by Mr. Guthrie on account of its situation. "The operator says he has cut his four inches, has turned up the edge of the gastrocnemius, and has performed his dissection under the head of the patient, which he has also about three from the bone. The artery is small as with arteries, turned down by a strong fascia, which 'seems to be an incalculable, over, or by the side of the artery, it will not do so separate it from the bone, and then to push it over, it comes below.' This supposes the fascia to be divided in the lower part, Mr. Guthrie doubts the separation of the two veins from the artery, and the passage of the gastrocnemius under the artery from within outward, so as to avoid the artery, without incalculable. 'If a tri-vascular vessel separates the most painful, difficult, bloody, tedious, and dangerous operations at home, the surgeon would be, hardly because it was not total to make a complete incision in the muscles of the calf of the leg, with incision, which, if made by accident, would be pronounced to be an absolute and very little danger, and not likely to lead to any dangerous detourments.' (See *Theses de la Faculté de Médecine*, p. 229.)

Instead of this method Mr. Guthrie advocates the following: An incision is to be made six or seven inches in length, through the gastrocnemius and tendons of the calf down to the bone. If the case is a gunshot wound, the extent of the incision is to be over a line with the skin edges, or if they are disjoint in each other, between them. The smoothings of the fascia piece of skin and the thick cellular membrane, turning the divided muscles to it, allows all parts of the leg to remain to be easily separated, and the flesh to be exposed to the vessel, artery, and vein. The tourniquet is now to be removed, and the bleeding stopped. When the artery is found, the knife may be applied perpendicularly to the bone, and the artery laid bare to the os calcis, and taken in external. (P. 235.) Perhaps the form of the incision is better described, in which part or that is equally necessary. Five or six inches and a half of the calf, or more, where the bone of the calf is very thick, will be enough to make the wound long.

Course of the Posterior Artery.—How to find it. Mr. Guthrie's description of the incision should also be made through the tendons of the calf to the bone, the cellular tissue of the leg, and the deep fascia under which has been found the artery will be found covered by the body of the flexor digitorum communis and the flexor digitorum profundus, and a half from the bone of the calf. These three having been exposed, the artery will be found close to the side of the bone. Above the point specified, the artery has very

the *tubalis posterior*, under the deep fascia interposed between it and the muscles of the calf. No nerve accompanies it.

Ligation of the Axillary Artery.—In preparing as this vessel approaches the lower of the axilla, it gives access to the vein, and becomes surrounded by those nervous fasciculi, by means of which one portion of the brachial plexus communicates with another. Before, to cut down to the artery in this place is the living body, and to tie separately, is acknowledged to be an arduous task. The difficulty is further increased by the distance of the vessel from the surface. Hence M. Manec decries any attempt being ever made to apply a ligature to the artery between the pectoralis minor and the lower border of the subscapularis. Independently, says he, of the difficulties of the operation, this part of the axillary artery would be unfavourable to its success, on account of the several branches which are given off from it, two of which the ligature must be placed.

Directly the axillary artery has arrived opposite the lower border of the great pectoral muscle, the difficulty ceases. Here the brachial plexus no longer exists; each of the different nerves arising from it has taken the course to its particular destination, and the artery is only covered by the integuments and fascia. Behind, it rests upon the tendon of the outer major and latissimus dorsi, in front, it corresponds to the coraco-brachialis, from which it is separated by the median nerve. At its inner side are the external circumflex nerve and the axillary vein, which sometimes consists of two or three branches, and renders the dissection of the artery more tedious. Further backward than the axillary vein are the ulnar and musculo-spiral nerves. The relation of these last nerves to the artery is of great importance to recollect, in order that neither of them may be mistaken for the median nerve.

In the operation of taking up the extremity of the axillary artery, the patient should be placed upon his back, and the arm raised from the side. An incision two inches and a half in length is to be made six or eight lines lateral to the anterior margin of the axilla, through the skin and subcutaneous cellular tissue. A piece of the linen is then to be filled up with the thumb, and an opening made in it by rolling transversely, close to the end of the forefinger; then a director is to be passed into the opening, and the fascia slit up to the extent of the external wound. If the fascia be tough and dense, so as not to afford convenient entry, Manec recommends the incision in it to be converted into a crucial one. These things having been accomplished, the further use of the knife is not necessary. The inferior edge of the wound being now filled up, the coraco-brachialis will be seen, and the median nerve at its inner side. This nerve being detached, the artery will be found behind it.

M. Manec offers valuable cautions with reference to the manner of avoiding the serious mistake of supposing the ulnar or musculo-spiral nerve to be the median. To escape this blunder, he very properly insists upon the prudence of proceeding backward from the coraco-brachialis, for in doing so the first nerve arrived at is the median. (See Manec, *Ymag. de la Lig. des Artères*, fol. Paris, 1822. Expt. of pl. 5.) In the case of a wound, however, the surgeon has not exactly the choice of the place for the application of the ligature to the axillary artery. Here he

must obey the rule of applying it to the wounded part of the artery, and putting one ligature above and another below the bleeding orifice; or, if the artery be completely severed, both its extremities will require to be tied.—(C.)

ARTERIOTOMY (from *Arteria*, an artery, and *tomo*, to cut). The operation of opening an artery, and taking blood away from the system in this manner for the purpose of preventing, alleviating, or curing disease. The only arteries of any use from which blood is ever taken in practice are the trunk and branches of the temporal artery, which lie in such a situation that, after the due quantity of blood has been taken away, the bleeding can be easily stopped by compressing the wounded part of the vessel against the neighbouring portions of the cranium. A narrow, sharp-pointed lancet, or a lancet, a basin for the reception of the blood, a compress, and a roller, are the only things required. In general, it is best to open the trunk of the temporal artery; but sometimes its frontal or occipital branch will yield blood enough. But, in many instances, it is better first to make a cut in the skin, and then puncture the vessel. In all cases the surgeon should recollect, 1st. That the temporal artery and its branches are covered by the skin, adipose cellular tissue, and a thin aponeurosis. 2d. That the trunk of the artery divides in the temple, about fifteen lines above the zygoma, and is situated about four lines in front of the trachea accliformis. 3d. That the frontal branch runs forward from its origin, and its occipital branch in the opposite direction. A good place for the puncture is about four lines above the zygoma. In taking away blood from the temporal artery or out of its branches, the surgeon should never forget the fact that the loss of arterial blood produces a more debilitating effect than that of venous; but, in many instances, the requisite quantity of blood cannot be drawn by this operation, as every surgeon of experience must have observed. In order to prevent the blood from trickling down over the bedding to clothes when it does not waste in a jet, the French make a little pillow with a piece of card for conveying it into the basin. After the proper quantity of blood has been taken away, a graduated compress and the nodose bandage are applied. The latter consists of a simple band, four yards long and two fingers' breadth wide, rolled up into two heads of unequal size. The smaller portion being applied over the graduated compresses that cover the wounded artery, the surgeon conducts the two heads, before and behind, to the opposite temple, where he crosses them in order to return to the point of departure. He now gives them a turn or two, which enables him to carry one over the strand of the band, and the other underneath the chin to the second side, where they meet and cross, as in the first incision. Thence they are conducted in the same course to the point of departure, and a second twist being effected, they are conducted for the third time to the opposite temple, and for the third time returned also horizontally and knotted: being conducted finally, one over the vertex and the other underneath the chin, the bandage is terminated by a few convolutions of the long end. (See *Cutler's Surgeon's Practical Guide in Disease*, and in *de Méthode d'Application de Bandages*, p. 46, Paris, 1826.) A graduated compress, and a few turns of a roller, rolled the forehead, temple, and occiput, are generally preferable to the foregoing bandage, the part of which extending under the

this is often very insupportable to the patient. In a few cases, notwithstanding pressure, the blood issues forth from time to time; and when this happens, it is best to cut the vessel completely across, which will enable its ends to retract and contract, and thus promote the process of union in closing them. In three or four days the wound is generally healed, but occasionally an abscess follows; an interesting memoir on which subject has been published by M. Desmoulins. (See *Mém. de la Soc. Méd. et de Statist.*, t. ix., p. 277.) In one instance, Cavallini effected a cure by dividing the vessel and coagulation. (See *Codex de Cas. Civ.*, t. ii., Firenze, 1792.) Sir Benjamin Brodie informed me of a case which he treated successfully in a similar manner. In the course of the present year, 1838, a woman was under my care at the North London Hospital for a temporal aneurism, which followed rapping on the temple. As the blood found its way freely into the tumor after one branch had been tied, I divided another, and applied a compress; the plan was then effectual. Sir Astley Cooper informed me of a temporal aneurism which was produced by a person falling with his temple against the corner of a table.

M. Blandin had a patient who, in consequence of arteritis, suffered acute pains, which extended to the top of the head, in the track of the superficial temporal nerve; this consequence, which is uncommon, may be relieved by lengthening the puncture or incision at each of its angles, or even cutting out a portion of the nerve. (See *Bist. de Méd. et de Chir. Pratique*, t. xiv., p. 472.)—G.]

[ARTERITIS. *Inflammation of an Artery.*—As the coats of arteries possess vessels and nerves of their own, and have an organization more or less similar to that of all the living parts of the body, they must be liable to inflammation, suppuration, ulceration, and gangrene, as well as other morbid changes, especially a deposit of calcareous or albuminous matter between the inner and middle coats. Arteritis, as contrasted with phlebitis or inflammation of veins, is much less perfectly understood, so far as the symptoms and diagnosis are concerned. It is very certain, however, that the arteries are not so liable as the veins, and, consequently, that arteritis is less frequent than phlebitis. Pathologists divide it into acute and chronic. The anatomical changes of the acute are, redness of the internal membrane of the artery affected, an effusion of plastic fibrine on its inner surface, thickening of its substance, and sometimes ulceration. When inflammation runs from a wound, or some other point of irritation, along the internal coat of an artery far towards the heart, it is like phlebitis; a formidable disease, rapidly producing great invasive fever, an extremely quick pulse, complete collapse, low delirium, and generally death. Arteritis, by completely obstructing a main artery and its principal branches, is sometimes a cause of mortification. The treatment of acute arteritis consists in bleeding, purgatives, diaphoretics, low diet, cooling diluent drinks, and perfect tranquillity. Digitalis, tartaric acid, and super-acetate of lead, are also prescribed on the principle of calmer the circulation; but, as Dr. Hope observes, they must be used with discretion. (See *Cyclop. of Pract. Med.*, part p., p. 119.) After the first violence of the inflammation has been checked, narcotic is sometimes given, so as to excite gentle but quick salivation.

Chronic arteritis is more common than acute. The internal membrane becomes thickened, softened, and of a deep, dirty red color. These appearances (says Dr. Hope) are not uniformly diffused, but more marked in the vicinity of calcareous and other degenerations. Hence some have supposed that these degenerations were the cause of the inflammation. There can be little doubt that they tend, in many instances, to keep it up; but it is highly probable that the degenerations themselves were originally caused by increased vascular action of a chronic nature. (See *of Pract. Med.*, pt. ii., p. 145.) The treatment of arteritis chronica is now generally believed to have its origin in chronic arteritis.—G.]

[ASPHYXIA (from α , privative of, and $\psi\upsilon\chi\eta$, the pulse). Denotation of the action of the lungs from the interruption of respiration, or, rather, of the effect produced by that function in the blood.

Asphyxia may also be defined to be a suspension of the phenomena of respiration, occurring primarily, and followed by that of all the vital functions, and frequently by death. The general causes of asphyxia may be arranged under three principal heads. 1. Asphyxia from deficiency of air. 2. From the air being unfit for respiration, yet not producing any deleterious effect on the economy. 3. From the respiration of some air which is deleterious. As M. Broussais rightly observes, however, the suspension of respiration, or the mode of death in the last case, is very different from what is exemplified in the first two, because it is, in fact, a kind of poisoning brought about by the action of a deleterious principle either on the nervous system or the blood, and the individual may perish though he is actually respiring air. (See *Théorie de Méd. et de Chir. Prat.*, art. Asphyxie.)

Cases of asphyxia admit of a classification, first, into those in which there is primarily a stoppage of the mechanical phenomena of respiration, and, secondly, into others in which the chemical phenomena are primarily interrupted. An example of the first mode of asphyxia, it will suffice to mention those in which the nostrils of respiration are cut off. 1. This happens when a heavy mass of earth or other solid matter falls upon a man, and induces great pressure on the chest or abdomen. 2. When the nervous influence does not extend to these vessels, as when the vertebra spinalis is injured high up, or the phrenic nerves have been paralyzed by the effect of lightning. 3. When the voice muscles are in a state of inaction from the influence of intense cold. Asphyxia, from the passive expiration of the lungs not taking place, may be exemplified in cases where the abdominal viscera are forced through an accidental or natural opening of the diaphragm into the chest, or when the lungs are compressed by fluid in the cavity of the pleura, and various other cases.

Asphyxia depending upon the primary suspension of the chemical phenomena of respiration is of two kinds. In one, it arises from some mechanical impediment to the entrance of air into the lungs, as in cases of foreign bodies external the trachea, intertension, strangling, &c.; in the other, it depends upon a deficiency of air fit for the purposes of respiration.

Asphyxia may be the original affection, or it may be only the termination of another disease. Thus a person is attacked by convulsions, and dies of asphyxia, caused by accumulation of the lungs; or he is seized with pleurisy, and is ultimately destroyed by an effusion of serum fluid in

the chest. (See *M. François in Dict. de Méd. et de Chir. Pratique*, Asphyxie.)

As the salutary effect of respiration depends upon the air which is inspired containing a due proportion of free oxygen, the deficiency or absence of this element must necessarily produce asphyxia. On this principle, azote, hydrogen, carbonic acid gas, and air too highly impregnated with carbonic acid, will cause asphyxia. Carbonic and some other gases not fatally also, on the principle of being positively deleterious to life when introduced into the vessels. One reason in which asphyxia may be occasioned is by constriction of the lungs of warm-blooded animals not having an organization qualifying them to derive from the oxygen contained in water the salutary influence on the blood which they collect from the respiration of atmospheric air.

Asphyxia may likewise arise from various circumstances preventing the entrance of air into the lungs, as the lodgment of a foreign body in the larynx, trachea, or oesophagus; a swelling of the mediæstinal of the lungs; a constriction of the organs and the trachea with fibrine, as in croup; tumors formed near, or pressing upon some part of the respiratory tube, and pressure upon the same organ from any other cause, as is exemplified in strangulation. It has been explained that some causes of asphyxia operate by destroying the mechanism of respiration, that is, by paralyzing the muscles concerned in this function, namely, the diaphragm. It will, at the same time, paralyze the other principal muscles concerned in producing the respiratory changes in the dimensions of the chest; and, consequently, a fatal asphyxia must take place. This was well illustrated in a case lately brought into the North London Hospital. The child of a youth, aged fifteen, was caught by the wheel of some machinery, which drove his neck with great force against the works, and, at the same time, curved violent strangulation. In about one minute the hæmorrhoidal was cut through and the constriction removed; he was brought to the hospital with his respiration stopped, and asphyxia from this cause. Attempts were made to restore respiration and the action of the heart, first, by blowing air into the lungs through the nostrils. Whenever this was done, the action of the heart returned, the pulse rose, and the livor of the lips and countenance disappeared, but as soon as the inflation of the lungs was discontinued, then the pulse sunk so as to become scarcely perceptible, and the skin assumed the purple colour again. Finding that this happened repeatedly, a suspicion was entertained that the cervical vertebra had sustained injury, but, in order that the inflation of the lungs might have every chance of doing good, in the event of other injury not existing, I performed tracheotomy, and air was introduced into the lungs with a pair of bellows and a tube. All this, however, was in vain; and galvanism was equally unsuccessful. The boy was kept in a state exhibiting signs of life for about six hours from the period of the accident; but his temperature continuing to get lower and lower, he at length sunk. In the post mortem examination, a fracture of the arch of the third cervical vertebra, a laceration of the front ligament of the spine, an effusion of blood on the medulla, and also another effusion behind it, - placing, were detected.

Formerly, the cessation of the action of the heart in hanging or drowning was referred to a mechanical impediment to the transmission of blood through the lungs to the left cavities of the heart. But the experiments of Goodwyn and others prove that no such mechanical obstruction exists, and that, even after the highest expansion, the air remaining in the air-vessels of the lungs distends them sufficiently to permit the blood to circulate freely through them. The real operative cause was of the interruption of those distal changes which atmospheric air produces on the blood while circulating in the pulmonary vessels, and which convert it from venous to arterial blood. In fact, the blood, which in asphyxia thus acquires its venous character, does for a time pass through the pulmonary circulation, and is conveyed into the left ventricle, which propels it into the aortic system of arteries. But this blood, which is thus substituted for arterial, has deleterious properties, depriving the organs to which it is sent of the power of performing their respective functions. Secondly, irritability, together with all the physical and vital actions depending upon them, are suspended. (See *Rogee in Cyclop. of Pract. Med.*, art. Asphyxia.) From the investigations of Bidart, it appears that the primary effect of the circulation of venous, or what he calls black blood, is on the brain, and that this effect extends through the intervention of the brain, to the whole nervous system. Loss of sensibility therefore precedes the suspension of the action of the heart, and takes place as soon as the venous blood sent into the arteries reaches the brain. (See *Bichat, Recherches sur le Viv et le Mort*.)

The face of a person who has been drowned is a general pale, though slightly livid. A frothy liquid, and some water, are found in the trachea, bronchia, and air-cells of the lungs; the latter organs are of a violet colour, but contain less blood than where asphyxia has been occasioned by carbonic acid gas; the right auricle and ventricle are filled with black blood, as the stomach there is generally more or less water, which has been swallowed; the surface of the brain is of a darker appearance than usual, but its vessels not particularly turgid; and the air remaining in the lungs contains little oxygen. (See *J. P. Berger, Éclaircissement sur l'Asphyxie par Submersion*, Genève, 1800; *Goodwyn's Constructions of Life with Respiration*, p. 19.)

When the person, at the time of falling into the water, was intoxicated, stunned by a blow on the head, or in a state of syncope, there can have been no struggle. Under such circumstances, the trachea will contain a little water, but not froth; the lungs will be of their natural colour, and not much expanded; no water will be found in the stomach; and the blood in the venous system will not be so disproportionate to that contained in the arterial. As Dr. Rogee justly observes, the great discovery in these and other circumstances "will enable us, perhaps, to explain the differences that are met with in the time during which the body may remain under water compatibly with the possibility of restoring life. If the submersion have not exceeded five minutes, and no blow against a stone or other violence has occurred to counterbalance the effects, our efforts at resuscitation, if properly conducted, will generally be successful. After a quarter of an hour, recovery is not very common; after twenty minutes or half an hour, it may be considered as nearly hopeless. The longest pe-

not recorded in the Reports of the Bannock Society is three quarters of an hour. On the other hand, some, who have been only a few minutes under water, cannot be restored to life, even by the prompt application of proper means." (*Dr. Roger, in Cycloped. of Pract. Med.*, article *Asphyxia*.)

In the endeavor to resuscitate a person whose animation has been suspended by immersion, the wet clothes should be promptly removed, and the body covered with blankets and placed on a table, with the head and chest raised; the nostrils and mouth are to be freed from froth, and kept perfectly unobstructed. The lungs are then to be inflated with the kind of bellows employed by the Bannock Society, and provided with a stout flexible tube, one end of which is adapted to the orifice of the bellows, and the other to a silver tube, designed for introduction into the nostril. As the glottis is open, air, conveyed into one of the nostrils, while the other and the mouth are closed, and the larynx is pressed towards the vertebra, so as to close the oesophagus, must necessarily pass into the lungs. The wings being thus filled, are next to be emptied, by an assistant compressing the chest and expelling the air. The same operations are to be repeated until natural respiration begins, at which time and other approved measures have been tried at least six hours. (*Dr. Chervin, On an Asphyxied Dog*, &c.) When this method fails to fill the lungs with air, tracheotomy may be performed, but in the opposite case it is not necessary. As the body is insensible, there is, indeed, commonly little or no difficulty in passing any kind of tube of moderate diameter and proper length into the glottis when the tongue is drawn forward, and tracheotomy, under these circumstances, cannot be needed. Thus, with an ordinary silver catheter, air may be blown into the lungs. Together with inflation of the lungs, gentle friction of the body with warm flannels or the hand, stimulating the nostrils with hartshorn, and injecting warm stimulating fluids into the stomach with a syringe and tube passed down the oesophagus, are plans generally recommended. Slight shocks of electricity or galvanism through the breast and diaphragm may also be tried, if the apparatus be ready at hand.

After the breathing has been restored, the patient is to be watched, but he yet fall a sudden victim to a returning accumulation of black blood in the brain, or to the violent effects of reaction in the system.

The treatment of persons whose animation is suspended by strangulation is the same as that of persons in a similar condition from immersion. Here, however, the failure of the diaphragm of the brain may render bleeding indispensable.

In cases of asphyxia depending upon obstruction of the glottis, larynx, or trachea by disease, foreign bodies, or tumors, tracheotomy or laryngotomy, according to circumstances, is frequently the only means by which life can possibly be saved. (See *LARYNGITIS* and *TRACHEOTOMY*.)

The treatment of asphyxia from carbonic acid gas consists in removing the body immediately into the fresh pure air, sprinkling it with cold water if its temperature be high, giving it, and endeavoring to restore the breathing by blowing air down the glottis; oxygen gas, if at hand. Differences of opinion are entertained about the utility of bleeding.—C.]

(*ATROPHY* from α , privative, and $\tau\rho\phi\acute{o}$,

nutrition). A deficiency in the nutritive powers of a part, in consequence of which its natural dimensions are reduced, and the number of its constituent molecules diminished. (Treated in *Cyclop. of Prac. Med.* on *Atrophy*.) According to another pathologist, atrophy is degeneration of growth, deficiency in the size and weight of a part, and commonly of one or more of its usual constituents in particular. (*Magn. Oulien, of Human Pathology*, p. 16.) When the functions of organs cease or are long suspended, an atrophy of them usually follows. Thus, in a limb kept for a long while unexercised in consequence of disease, the bones suffer atrophy as well as the soft parts. But certain states of disease and injury frequently lead to atrophy of various organs and tissues. This fact is often exemplified in the testicle. Wounds of the scrotum and back of the neck were remarked as *Larrey* in Egypt to be often followed by atrophy of this organ. The want of a free supply of blood and nervous energy leads necessarily to weakness and atrophy of parts. In old age, various parts undergo what is termed *senile atrophy*. Thus is advanced life, the ovaries and mammary glands are reduced to mere rudiments.

According to Dr. Carnwell, atrophy "is the modification of bulk which takes place in consequence of a diminution in the quantity of the solid materials which enter into the healthy composition of organs and tissues." This diminution of bulk, which constitutes the essential physical character of atrophy, is described by him as depending upon diminished exercise of the nutritive functions. (See *Carnwell's Illustrations of the Elementary Forces of Disease*, p. 107.) In this valuable work, one of the most correct ever published on this interesting branch of pathology, notice is taken of certain forms of *essential atrophy*, as exemplified in anæsthesia, and anæsthesia the consequences of the forming process having been arrested at certain periods of the evolution of particular organs. Dr. Carnwell most ably adverts to the atrophy, or even total disappearance of organs, soon after birth, which performed functions essential to the sustenance of the foetus, but which are now no longer necessary to the maintenance of life, as the ducts of the testes, umbilical arteries, the thymus gland, supra-renal capsules, &c. Different from these two forms of atrophy is that which, as Dr. Carnwell observes, takes place in advanced life, "as the fulfilment of a general law of nature, as successively manifested in the limited duration of all organized beings, which, having attained the maximum of their development, decline after a variable period of time, and tend gradually towards decay." *Senile atrophy*, as Dr. Carnwell terms it, is carried to a great extent in the vascular structure of the lungs, the spongy structure of the penis, the testes, the lymphatic and mammary glands, the uterus, and ovaries. The heart, in general, loses much of its weight; and at every stage of its experience knows, *Larrey* of the neck of the thigh bone is peculiar common in old persons, in consequence of the effects of *senile atrophy*. After seventy, the testis is diminished from $\frac{1}{2}$ to $\frac{1}{3}$ of its average weight, and becomes specifically lighter, and the trunks and branches of the nerves are reduced in size. The muscles, especially those of voluntary motion, participate likewise in the general decay, and so do the bloodvessels, which always bear a relation to the increased or reduced size of the organs to which they are distributed.

This fact is exemplified in the size of the large, or the number of small, arteries being lessened. The general antemortem absorption of John Hunter, the atrophy of the whole body, or the inanition and emaciation from diseases deranging the important functions of digestion, respiration, and the qualities of the blood from leucæmia, putrid suppuration, and various fevers and organic diseases, I need not enumerate in this place. But, besides these forms of atrophy of

forming the white body, there are others which are local, and divided by Professor Cuswell into three classes:—1. Atrophy from a diminished supply of blood. 2. From diminished exercise of the function of nutrition. 3. From diminished exercise of the functions of the organ. For numerous original, philosophical, and practical remarks on these heads, I refer to Cuswell's *Illustrations of the Extreming Power of Disease*, fasc. 10.—C.]

B.

BANDAGES. The surgical world are indebted to Professor Duff, of Kentucky, for the first estimation and extensive adaptation of the bandage as a therapeutic agent. Its early application after recent injuries and operations will be found of great assistance in controlling the circulation and facilitating the cure.

During the year 1830, Dr. H. Chase, of Philadelphia, introduced to the profession a novelty in the construction of suspensory bandages. He substitutes non-elastic (linen) bandages for those commonly made of silk, cotton, or other elastic materials. They vary in shape, both those extraordinary size, the size in each instance being adapted to the size of the scrotum, and the band supporting the sac passing upward over each groin, and around the body above the anterior superior iliac spine process of the ilium.

The principle of action resides in the constancy and immovability of the support and pressure, by which the undue contents of the enlarged spermatic veins are expelled from these vessels. He has seldom found these bandages useful in relieving patients from all the painful symptoms attendant upon varicose, and, in an equal number of cases, to eradicate all traces of this complaint.

A full description of this instrument, together with its mode of action, is given, accompanied with cases, in the Appendix to the *Final Report of the Committee of the Philadelphia Medical Society on the Radical Cure of Hernia by Truss*. Republished, with Notes, by Hiler Chase, M.D., p. 217.—Review.

[BLADDER. The operation of cutting into the membranous portion of the urethra, behind the stricture, seems to me one of the greatest improvements in modern surgery; for, as it is chiefly in a few cases of stricture that an artificial urethra for the time is required, the new plan, which, as compared with a wound of the bladder, is a trifling injury, readily obviates all necessity for penetrating the bladder in any way.

This plan was first adopted and recommended by Sir Astley Cooper, and it afterward had an advocate in Sir Charles Bell.

I lately placed in the Museum of University College a scirrhous testis, which I found in the bladder of an elderly man, whose thighbone broke as he turned himself in bed, in consequence of being weakened by the presence of a cancerous tumour upon it. (*Sir Med. Cur. Trans.*, vol. xvii., p. 51.)

BLADDER, HERNIA OF. See HERNIA.

Besides this case, the bladder in females is liable to prolapsus and inversion, through the menstrual currents.

BLADDER, HYDATIDS FORMED FROM.

This case is exceedingly rare. In one example, under Dr. Denon, the hydatids discharged from the vesicles were formed in the kidney. The symptoms were frequent desire to make water, and sometimes difficulty in making the evacuation, and pain about the tip, perineum, and clitoris. The pain in the perineum was generally felt six or seven hours before each hydatid was expelled. The expansion of the hydatids was pointed out by exhibiting twelve minims of diluted muriatic acid three or four times a day. The hydatids varied from a globular shape, and of the genus acanthocyst, and varied in size from that of a pea to that of a pigeon's egg. Probably they had enlarged after their descent into the bladder. (*See Liverpool Med. Journ.* for July, 1831.)

The following curious account of the post mortem appearances is an instance of this kind is given by Dr. Tyson: "Thereto, upon operation (says Dr. Tyson), we discovered a very strange sort of cysts, or bags, of the exact figure of eggs, of several diameters, some larger than goose eggs, others as big as hen eggs, to the number of twelve in all; and about eight of them white, and coped with large semis; all of them loose and free, without the least adhesion, either to one another, or the coat of the bladder. Nor could we imagine that this miserable patient could possibly make any water but what happened upon the breach of some of these watery tumours, when the bladder was crushed beyond its dimensions. The tumours were of the largeness of the small guts in children, so that they could easily admit two fingers into their cavity. One of the vesicles being opened, had a large cluster of small ova, as big as grapes, all coped with liquor. All the rest contained nothing but mucus." (*2 years in Philad. Trans.*, 1687.)

BLADDER, IMPACTS DISCHARGED FROM.

About two years ago I received from Mr. Law, of Penryn, Cumberland, many specimens of calcifications washed from a young woman's bladder, supposed by him to be portions of testis. But, on submitting them to the examination of Mr. Richard Owen, at the College of Surgeons, he ascertained, perfectly to his own satisfaction, that the substances were only pieces of the trabeculae of pyramis, or other small parts, cut and prepared so as to bear some resemblance to testis; and, consequently, that the woman is guilty of some trick imposture, from moroseness or other inexplicable cause. Mr. Law seems convinced, however, that the case is different from the view of it taken by Mr. Owen.

BLADDER, RUPTURE OF THE.

Many examples of this accident, occasioned by blows, or sudden violent pressure on the hypogastric region, and followed by fatal extravasation of urine, are on record. So fatal is the occurrence, that Dr. Harrison is not aware of any instance, the particulars of which are published, having had a favourable termination. (See *Dublin Journal of Med. Science*, vol. ii., p. 320.) The urinary bladder, in its empty and contracted state, as he correctly observed, lies so deeply in the male pelvis as to be almost perfectly secured against any injury or accident except that of a gunshot wound or a surgical operation. When, however, it becomes distended with urine, it rises up above the pubes, presents forward against the abdominal muscles, and is in a position much exposed to external injury. In this state, also, its coats are tense, expanded, and thin; conditions in which their tissue is more easily ruptured. Excluding from present consideration penetrating wounds and lacerations by spiculae of fracture of the os pubis, the bladder is generally burst by violence, applied directly to the hypogastric region, as by a blow or fall on this part, or the heavy pressure of a cart or carriage wheel. In the museum of University College are two specimens of ruptured bladder; in one the accident was occasioned in the following manner: a man who had been drinking, and whose bladder was very full, went out of the house where his party was, but it being dark, he struck the hypogastric region against a post which he did not see. The consequence was the rupture of the bladder. The other specimen was taken from a fine young man, a patient of my own; the injury having occurred whilst the bladder was very full of urine, as he was wrestling with another person, whose knee, in the fall, made violent pressure on the abdomen, just above the pubes. Also, the accident has sometimes been caused by a general concussion of the whole frame, such as a fall from a height, without any direct force acting on the caecal region itself. (See *Chambers's case in Dublin Hospital Reports*, vol. ii.) Again, the bladder may be ruptured by violent exertion, and repeated straining to urinate it when overdistended, in consequence of some obstruction to the flow of urine, or during the violent effects of parturition. Lastly, it sometimes gives way from gangrene, when it has long been in a state of forced distension, or when, being in a state of ptosis, it is subjected to the long-continued pressure of the uterus during a protracted labour, or, in the earlier periods of stove-potition, to the pressure on it caused by a retroversion of the womb, as exemplified in the cases recorded by Dr. William Hunter. (*Med. Obs. and Inq.*, vol. ii., and v., Lond., 1771; *Harrison in Dublin Journal of Med. Science*, vol. ii., p. 322.) In retention of urine, a rupture of the bladder from straining to urinate, is but a common event. One instance of it is mentioned by Sir Benjamin Brodie (*On the Use of Urinary Organs*, p. 27), and another by Sir Keppell Home. (*On Stricture*, vol. i., p. 240.) But, as Dr. Harrison observes, it is doubtful whether, in the latter case, the opening in the bladder was the effect of a violent laceration, caused by muscular exertion, or of some preceding oblique or gangrenous affection of the particular point where the organ gave way. Generally, however, as retention of urine from stricture, when the urine becomes effused, it is not from a rupture of the

bladder, but from that of the urethra behind the stricture, or in the immediate vicinity of the prostate gland. (*Harrison in Dub. Journ. of Med. Science*, vol. ix., p. 322.)

It would appear from Dr. Harrison's observations, that, when the distended bladder in the male has been ruptured by a fall or blow on the hypogastric region, or by a general concussion, that portion of it which is bounded by the peritoneum has very generally been the seat of rupture; the urine has consequently been effused in the abdomen, and the patient has been destroyed by peritonitis (p. 324).

The following is the explanation offered by Dr. Harrison of the fact that, when the bladder is ruptured by a blow or general concussion, the laceration is always found in that part of the organ which is covered by the serous membrane. "The several tunics of the bladder allow of considerable distention, but least of all the peritoneal: when, therefore, the bladder becomes fully distended, and is then subjected to any sudden or violent compressing force, this tunic, which is then tense, and comparatively unyielding, will crack, while the subsequent tunics which are connected to it will be torn along with it; whereas, in other situations, when cellular tissue occupies the place of the serous membrane, the coats of the bladder will yield considerably before they give way or admit of laceration." (See *Dublin Journal of Med. Science*, vol. vi., p. 321.) The bladder being perched forward against the prominence of the os pubis in the male, seems to Dr. Harrison also to account for the rent being usually in the posterior region of that tunic. The entry of the accident in females is ascribed by him to the greater size of the pelvis, the cavity of which is yet so imperfectly occupied by the bladder when this is full of urine. Nor (says he) does the bladder incline so much backward as in the male; on the contrary, it inclines more forward, and enlarged more in the transverse direction, while the uterus and associated broad ligament serve to break the shock of any external violence applied to the hypogastric region, and so prevent the direct concussion of the bladder across the sacral promontory." (Vol. vi., p. 321.) The comparative infrequency of a rupture of the bladder in children and boys is ascribed by Dr. Harrison to their rarely suffering the bladder to become much distended with urine, and to put to the smaller size of the sacral promontory, and to the bladder, when full, lying in early life more in the abdomen.

With respect to the diagnosis of the kind of rupture of the bladder now under consideration, it is judiciously observed by Dr. Harrison that, as it is the effect of only two species of injury, the account of the accident will afford useful information. Thus, says he, every case on record has been the result either of some force directly applied to the abdomen, or of a general concussion of the whole frame. In this latter case the injury is more likely to be overlooked, particularly if the individual has suffered in any other and more obvious manner; hence, after such a calumny, the attention of the practitioner should be early directed to the urinary discharge, and, if there be any inability to pass the urine, and a desire to do so, the catheter should be introduced. When the rupture has been the effect of violence directly applied to the hypogastric region, the symptoms are more obvious. The patient himself is often aware of the accident; he knew that his bladder was full at the time of

the injury; perhaps he felt it burst within him. Then the sensation of sinking and sickness, the pain in the abdomen, and the peculiar feeling about the perineum, are all circumstances indicative of the rupture of a blood vessel. In addition to these symptoms, there will be a desire to make water without the power of doing so; great pain in the body and perineum during the attempts to urinate; at the bladder, the fulness being difficult and not circumscribed, as in common retention of urine. When a catheter is introduced into the bladder, it meets with a peculiar resistance, and the urine flows through it, not in a stream, but as if it merely filled and overflowed the instrument slowly, some time only in a few drops, at another in considerable quantity. "This difference depending on some alteration in the direction of the instrument, or in the degree of pressure with which it is pushed against the bladder, whereby the relation of the rupture must be ascertained, and more or less of the abdominal and pelvic urine be discharged." (See *Harrison in Dub Journ. of Med. Science*, vol. ix., p. 277.)

In the case, recorded by Mr. Casack, only a few drops of urine could be drawn off with the catheter on the day of the accident. On the next as much flowed at first; but, by changing the direction of the instrument, and on making pressure with the finger in situations, those few were discharged. On the third day, as all the symptoms continued unabated, the abdomen was punctured in the lower left, midway between the umbilicus and the pelvis; and a large quantity of clear urine issued, and, at the same time, it flowed freely from a catheter pushed in. The relief was only temporary, the patient having died delirious on the eighth day. On dissection, marks of intense inflammation were noticed in the hypogastric region, where the intestines were glued together into one mass. At first no urine was seen, but, on breaking the adhesions and raising up the intestines, about a pint of it was spunged out from between the rectum and the bladder. "The pelvic portion of the peritoneum was completely coated with lymph; the bladder was contracted and empty; the rupture, about an inch in extent, was in its posterior part and right side, and in an oblique direction." (See *Casack in Dub. Hospital Reports*, vol. i., p. 312.)

In the post mortem examination of a case under Dupuytren, traces of severe inflammation were observed in the hypogastric region. Adhesion existed between the abdominal paries and the bladder, and the sides of the latter and the adjacent viscera were all so agglutinated together, that a kind of pouch was formed, considerably advanced in organization, whereby the urine was circumscribed, and effusion to any further distance prevented. (See *Archives Gén.*, June, 1834, p. 281.) In general, the bladder, through the seat of injury, is small but little inflamed, except at the posterior portion of its serous coat. (See *Harrison in Dub. Journ. of Med. Science*, vol. ix., p. 276.)

In the treatment, the principal indications are to withdraw, if possible, the effused fluid from the abdomen; to prevent, if possible, any return or increase of such effusion; and to resist and subdue that irrepressible and very fatal affection peritonitis. With this view, any accumulation of urine in the bladder should be prevented by the introduction of an elastic gum catheter of full size, with a long and large curve; and if, by changing its direction or other measures, its

neck can be passed through the rent, or made to reach its vicinity so as to open it, a considerable quantity of urine may be drawn from the cavity of the peritoneum. Pressure with the finger is and is also to be tried. (See *Harrison*, vol. ix., p. 279.) In the case which I attended, a catheter of full size was kept continually introduced, in this way we endeavored to lessen the exciting cause of the inflammation, which, however, is sure to follow the effusion of an irritating fluid as the urine. Inflammation must, therefore, be treated by local and general bleeding; calomel, opium, and mild saline purgatives given with the refrigerating mixture. If the disease advance, and the pain in the abdomen become more intense, with swelling and distention, ought the surgeon to perform paracentesis? As Dr. Harrison remarks, this has been done in two instances, but without success. "The urine which is effused is principally lodged in the pelvic cul-de-sac, and is more or less confined to that region, partly from its depending position, and partly from the adhesions which, we have reason to expect, under proper and active treatment, may have been formed between the bladder and the adjacent viscera of the upper orifice of the pelvis." This view leads Dr. Harrison to consider cutting a small opening through the rectum into this cul-de-sac the best and safest plan for the discharge of the irritating fluid. Here a new cavity has been formed, covered internally like an abscess; and the opening is not to be regarded as extending into the general cavity of the peritoneum. The operation might be done with a trocar, or a long curved bistoury, with a sheath, and a cutting edge only on its extremity. The patient being in the recumbent posture, with his knees drawn up and somewhat separated, the finger of the left hand might be passed up the rectum as far as possible, and forced against its fore part. The catheter in the bladder might also assist in guiding the finger to the cul-de-sac behind that organ. The cannula of a long curved trocar might next be passed along the finger, and, when its extremity had been placed against the fore part of the rectum, exactly in the median line, the stylette might be pushed through it, and the peritoneum opened. Dr. Harrison conceives that the quantity of effused fluid would protect the small intestines from reach of the instrument; and he says that in the cases which he has examined, he did not find any of their convolutions in the pelvis. Supposing this opinion were ever attempted, ought the cannula to be left in the part? or ought it to be withdrawn, and the catheter trusted to for the prompt discharge of the urine afterward? The latter method is preferred by Dr. Harrison. (See *Boer, Med. Obs.*, t. ix., p. 61; *C. Matignon in Med. Communications*, vol. 2., p. 284; *Casack in Dub. Hospital Reports*, vol. i., p. 312; *Dupuytren, Archives Gén.*, June, 1834, p. 281; *Jackson in New. of Med. Soc. of Lond.*, vol. iii., p. 543; and particularly *Dr. Harrison's Case and Obs. in Dub. Journ. of Med. Science*, vol. ix., p. 248, in which I am indebted for the chief information in the foregoing article.)—C.T.

BLEPHAROPLASTIC. Doctor Alfred C. Pool, of New-York, has cured two aggravated cases of ectropion of the lower lid, occasioned by the contraction of cicatrices, resulting from burns, by means of the blepharoplastic operation. An incision was first made by which the lid was detached from the cheek throughout nearly its whole extent. A triangular portion of

the everted lid was then secured, and the edges of the wound in the lid brought together with a suture. A vertical flap was then formed from the integument, covering the nuchal muscle, and sutured upon itself so as to be inserted between the lid and the cheek, where it was retained by sutures. The edges of the wound from which the flap was taken were also brought together in a similar manner. The deformity resulting from the excision after the healing of the wounds was very trifling, compared with that which had been removed by the cure of the ectropion.

An account of the first of these cases was published, with engravings, in the *New-York Medical Gazette* for January 19th, 1842.

During the last year, Dr. J. M. Warren, of Boston, has performed this operation for restoring the lower eyelids, which had been partially destroyed by burns, in two cases with entire success.

Dr. Geo. McClellan, of Philadelphia, has repeated this operation fifteen times, and with the most gratifying results in removing frightful deformities.

Dr. Mutter, of Philadelphia, has also operated in several cases with gratifying success, and Dr. Horner, of Philadelphia, reports a successful case in the *American Journal* for 1837.—[Edison.]

[DILATERS. In the North London Hospital, the nitrate of silver is often used for making blisters, as particularly recommended by Mr. Higginbottom. It causes less irritation, and its effects are more prompt than those of cantharides. It may also be used in persons in whom cantharides produce strangury. It excites a copious discharge, without heat or pain after the first few hours, and the vesicated part heals about the fifth day, no suppuration having been occasioned. (*See Hypodermic use of Nitrate of Silver*, p. 161.) By means of the application of diluted silver, repeated every six or eight days, and of perfect quietude of the part, secured by means of a splint and bandage, many a diseased joint has been cured in the North London Hospital.

"In applying blisters to infants," says Dr. Cumming, "we must take particular care not to allow them to remain on for more than three or four hours. When a blister is applied for a longer period, excessive general irritation is apt to be induced; and such is the delicacy of the infant's skin, that the blistered parts not infrequently become gangrenous. Under such circumstances, the death of the child has been sometimes the consequence. Though vesications may not have formed at the time when the blister is removed, they generally take place after the application of the dressing. In some habits the blistered surface takes on an unhealthy action, and runs into eating and antiseptic ulcers, which are long in healing. In such cases I have found an emollient poultice when the inflammation is considerable, and afterward the black and yellow ointment, the most useful applications. In infants of an irritable habit, it will sometimes be advisable to dilute the blistering plaster with an equal quantity of the emplastum cantharidis." (*Ob. Essaying in Theory of Acute of Coll. of Physicians, Ireland*, vol. 8, p. 55.) *See Parry's Pharmacology*, vol. 6, p. 186, ed. A. A. T. Thomson's *Dispensatory*, and *Elements of Mat. Med.*, ed. 2. *See Hypodermic use of the Nitrate of Silver*, p. 161, ed. 2, 8vo, 1829. *May's Outline of Human Pathology*, ch. 1.—C.)

[BONES, EXCISION OF. This operation is sometimes applicable to the articular portions of

bones, but still more frequently to other parts of them. The circumstances under which it is performed for the removal of diseased or very severely injured joints, and the plans then to be adopted, will be hereafter considered. (*See JOINTS, EXCISION OF*.) Neither shall I dwell upon the removal of the projecting ends of broken or dislocated bones, nor upon saving of the extremities of old ununited fractures (objects noticed in the account of *Dislocation and Fracture*). In the articles *Amputation* and *Gun-shot Wounds*, I have called the reader's attention to the presentworthy method of cutting down to, and removing all loose splinters of the os trephos, and even the sharp ends of that bone itself, from certain gunshot injuries of the shoulder, as so frequently to obviate the necessity of amputating the limb. The cases demanding the removal of portions of the skull, and the manner of accomplishing it, will be described under the head *Trephane*. Towards the conclusion of the observations upon *Amputation*, some account has already been given of the manner of certain kinds of the hand and foot. It is difficult, as M. Malgaigne observes, to lay down any precise directions for the removal of the bones of the femur. The following plan was adopted by M. Roux, the father, by an extensive class. Over the cuboid bone there was first a line in inch diameter, and another between the third and fourth metatarsal bones, resulting from an incision made a few days previously for the discharge of an abscess. A probe penetrated into the cuboid bone. An incision was made along the inner side of the foot, and extended across the wrist, from the posterior third of the fifth metatarsal bone to above the anterior tubercle of the os calcis; and, as the incision already made for the abscess could now be made serviceable, this and the other incision were completed by a transverse cut, and the square flaps reflected. The diseased bones were thus brought into view, and it was necessary to remove the cuboid, the third cuneiform, the posterior end of the fourth metatarsal bone, the inner side of the extremity of the fifth, and the articular surface, by which the os calcis is united with the cuboid bone. The tendons of the peroneus longus was preserved. The flaps were then laid down, and united with two sutures. The patient, who was young, got completely well. The vacuum occasioned by the extraction of the bones was filled up by a substance which afterward ossified. In the end, the patient was able to walk well, the foot having retained its natural shape and motion. (*See Malgaigne, Mem. de Méd. Opér.*, p. 231.) The operation of removing the metatarsal bone of the thumb, or the metatarsal bone of the great toe, is not deemed by Mr. Liston an advisable proceeding, because the rest of the thumb or toe is left without support, and is useless. He has seen cases treated in this way, but the result was unsatisfactory. However, Mudge removed the whole of the first metatarsal bone on account of cancer, and M. Harter did the same thing at the Val de Grâce after a dislocation of the bone, and in both cases the result was in every respect successful. (*See Malgaigne, Op. cit.*, p. 244.) The extraction of the metatarsal bone of the thumb has been performed with success by M. Roux and M. Blandin. The thumb was at first shortened and useless, but gradually became capable of executing all its natural movements. (*See Malgaigne, Mem. de Méd. Opér.*, p. 232.) An incision is to be made along the radial edge of

the bone, and to extend about half an inch beyond each of its articulations. Then the integuments and exterior tendons are to be detached from its distal, and afterward the muscles from its palmar surface. While an assistant holds aside the flap of the wound, the surgeon opens the outer side of the carpal joint with the point of the knife, cuts through the tendon of the long abductor, which is inserted into the metacarpal bone, and then carries the knife completely through the joint. He now tries to dislocate the bone outward, and to pass the knife along its inner side, so as to effect its total detachment from the carpalæ. Lastly, the articulation with the first phalanx is opened by cutting in succession the internal and external lateral, and the anterior ligaments. The radial artery may be avoided, but, were it wounded, the application of a ligature to it would be attended with no difficulty. The second is to be brought together, and the thumb supported in its natural position with soft pads placed in the palm. (See *Malpighi, Op. cit.*) *Excision of the anterior portion of the first metacarpal bone* seems to M. Blandin advantageous, because, when the root of it can be saved, the foot remains with a more solid support. A flap is formed at the inner side of the bone, with its base backward. The bone is exposed to the point where it is intended to divide it; even perpendicularly to its axis; then, detached from its connections from behind forward; and, finally, disarticulated from the phalanx. With respect to the phalanges of the other four toes, amputation is commonly preferred to excision of them; and so it is to excision of the heads of their metatarsal bones. (See *Malpighi, Op. cit.*, p. 262.) Although the removal of the metacarpal bone of the index and little fingers may easily be performed, by cutting along the outer margin of it, M. Malpighi is probably correct in stating that such an operation, in consequence of the subsequent shortening of the finger, would leave after it as much deformity as amputation would produce, and even greater weakness of the hand. This observation is not applicable, however, to the excision of the metacarpal bones of the middle and ring fingers, which will still retain their connection with the contiguous ones, and the strength of the hand be preserved. An incision is made along the dorsal aspect of the bone, by the side of the extensor tendon, which should not on any account be divided, and the disarticulation is to be begun at the knuckle. (See *Malpighi, Mem. de Med. Opér.*, p. 233.) The removal of dead, or softened and carious portions of the carpal and tarsal bones, Mr. Liston admits, is sometimes successful, but operative interference with these, or with many extensive and firm articulations, is not advisable, unless the soft parts be not largely involved, and the general health tolerably good. If the ligaments, nerves, and cellular tissue are much affected, Mr. Liston considers the chance of the discharge ceasing and of the return of health entirely hopeless. Amputation above the diseased parts will still be indispensable; and, in consequence of the more reduced and debilitated state of the constitution, this second operation is less likely to answer than if it had been undertaken earlier. (See *Liston's Essay*, part iii., p. 398.) It is right to mention, however, that after removal of the first phalanx of the thumb and the extraction of the fragments, M. Velpeau has known the part regain its motion. If an incision were necessary for the removal of the phalanx, it

should be made along the radial side of the thumb, and the metacarpal articulation, which is the looser one, being opened first, the phalanx should then be inserted outward, and dissected out. (See *Malpighi, Mem. de Med. Opér.*, p. 231.) In a few cases, Mr. Liston has removed several of the tarsal and carpal bones, as practised by Mr. Dunn, of Scarborough (see *Amputation*), in others, one, or a portion of one, with success. In one instance the greater part of the sesamoid was taken away along with the ends of the tibia and fibula. These contained a large opening across the joint, through which a seton was passed, to promote the gradual and piecemeal discharge of the remaining portions of diseased bone. The articulation could be seen through. The seton was gradually diminished, and the aperture closed. The foot was preserved, and the leg was somewhat shortened, but the limb proved extremely useful, though the ankle retained little power of motion. Mr. Liston, as well as many other surgeons, has also performed the *ex arthro*, and removed large portions of it. He has likewise taken away the cuboid bone, along with the base of the metatarsal bone or bones in connection with it. In some of these cases an excellent cure followed; in others, amputation of the foot was afterward necessary. (Vol. cit., p. 399.) Examples of the removal of extensive portions of the *ex arthro* are reported by Hey, Moen, and M. Roux. In the North London Hospital there was a young woman, in 1835, from the outer part of whose os calcis Mr. Liston removed a considerable piece with a trepan. The cure was a scrofulous canker. Some amendment followed; but the canker penetrated too far to admit of complete removal in this manner. A fine specimen of the same thing was lately put into my hands by Mr. Moen, of University College, the part having been finally amputated in the Newcastle Hospital. In one case, where the scapular base of the scapula was dislocated by an injury, occasioned by machinery, Sir Astley Cooper successfully removed that bone. The rule proposed by him for any analogous case is to take away one, or even two of the carpal bones, if displaced; but, if the mischief is greater, to amputate.

I am not disposed to bestow much commendation on such an operation as the *excision of the ribs*, notwithstanding the high and respectable authorities which may be quoted in sanction of it, with the exception of its performance in cases where a sequestrum is nearly or entirely loose. The most remarkable excision of the ribs yet recorded is that performed by Mr. Richardson, in 1818, on a medical officer, who was afflicted with cancer of the thorax. The middle portion of four ribs was removed to the extent of several inches. It was also necessary to extirpate the contiguous part of the pleura, which was very much thickened, and transformed into a cancerous substance. Thus the polypations of the heart within the pericardium were brought completely into view. The case afterward went on favorably for a time, but in the end proved fatal by a return of the cancerous disease. I strongly need advise British surgeons not to attempt any similar operation where the disease of a rib, or, indeed, of any other bone, is the effect of a primary cancerous affection of the soft parts. Such an experiment must inevitably terminate in the return of the original malignant disease, unless the patient's accelerated death happen not to leave sufficient time for this result. These observations are directed chiefly, however, to the

particular case here specified; and as the extraction of portions of ribs has been performed by several eminent surgeons with success, I conclude that circumstances may occur in which the plan is judicious. Not to lay any stress upon the instances of the practice in ancient times by Galen, Astruc, Sedillier, Lacet, Ferriar, &c., it has been twice resorted to subsequently by Richardson's operation, and with success, by Atanasi in Italy; also in the Hospitals Beaujon and La Charité at Paris, and by Dr. Mott, of New-York. The operation consists in extending the incision through the soft parts behind the extent of the diseased portion of the rib, both in front and behind, and then, after detaching the bone from the pleura at the point where it intended to divide it first, it may be sawed through with one of Hey's saws, or what will be more convenient, divided with a pair of cutting pliers. The divided end of the bone should then be united outward, and separated from its connections, so as to facilitate the safe division of it beyond the extremity of the disease. A principal thing in the operation is to avoid injury of the pleura as much as possible.

In 1825, the removal of the scapula was accomplished with complete success by Dr. R. Bell, of Virginia; and in 1826, M. Velpeau had a case in which he was desirous of performing a similar operation, on account of disease entirely restricted to that bone, but the patient performed amputation. (See *Velpeau, Nouv. Éléms. de Méd. Opér.*, t. 2, p. 365.) An incision is made along the outer and anterior part of the scapula. The edges of the wound are to be held apart, and the muscles detached from its anterior and posterior surfaces a little below its middle part, where it is most superficial; a chain-saw is to be used; a director now being introduced on the outer side of the bone, will serve to convey the chain-saw behind it. In the place specified, the bone is sawed through, and the two fragments carefully dissected out. If sufficient ribs were not obtained for the action of the saw by the longitudinal incision, a transverse one should also be made. (Velpeau, &c.) A strong pair of cutting forceps would divide the radius with less difficulty than a chain-saw.

In an example of removal of the outer third of the clavicle, M. Velpeau removed the scapular portion of it. Two incisions in a cruciform form, and four inches long, were made, the flaps raised, the acromio-clavicular ligaments, and some parts of the origin of the deltoid and trapezius divided. The bone was then raised with a lever passed into the joint, and its detachment completed. M. Malgaigne conceives that a better plan would be to make first an incision parallel to the clavicle, but a few lines below it, and ending at the acromion, and then another shorter one at a right angle with this extremity of the first, so as to form a triangular flap. Instead of a chain-saw, the clavicle may be very safely divided with one of Hey's saws or a pair of cutting pliers, care being taken to pass a flexible copper spoon under the bone to protect the subjacent

parts from the saw. The interosseous ligament was torn through, so as to free the distal end. The patient was alive six years, when the operation, and in good health.

The whole clavicle affected with osteosarcoma was removed by Dr. Mott, of New-York. The tumour was of the size of two fists and reached upward nearly to the hyoid bone and angle of the jaw. A semicircular incision, with its convexity downward, was made below the swelling, from one end of the bone to the other. Another incision was next made above the tumour, from the acromion to the external margin of the external jugular vein. The platysma, and a portion of the trapezius having been divided, a director was passed under the bone near the acromion, and a division here effected with a chain-saw. Not being yet able, however, to display the tumour, Dr. Mott, with the aid of a director, extended the first incision toward it, and having applied two ligatures to the external jugular vein, and cut it through in the interspace, he next divided the clavicular portion of the sternocleidomastoid muscle, and found it necessary, also, to use and divide the internal jugular vein. The clavicular vein, and therefore duct were separated from the diseased parts with the handle of the scissor. Lastly, the great pectoral muscle, the costo-clavicular ligament, and the serratus muscle having been divided, the disarticulation of the distal end of the clavicle was accomplished. The bleeding required forty ligatures in its suppression. In six weeks the wound was nearly healed, and the patient afterwards, with the aid of a mechanical substitute for the clavicle, retained the power of moving the limb with but little impediment.

The removal of the scapula to a greater or lesser extent, has been performed on several occasions. In one instance, a considerable portion of the scapula was removed by M. Jansen, on account of a tumour involving it. Two semi-elliptical incisions were made so as to circumscribe the swelling; as much skin as possible was dissected up and saved; the tumour and bone were then detached from their connections in every direction, as low down as the linea sub-scapularis. The attachments of the trapezius, supra and infra spinatus having been divided, and the portion of the bone above the spine ascertained to be sound, all the other diseased part was sawn off, and the shoulder-joint left uninjured. One more incision was necessary to expose the whole of the tumour, and facilitate its excision. The wound was altogether six inches in breadth and nine in length. The motion of the shoulder was preserved. A large tumour of the scapula was removed two or three years ago by Mr. Ernie, but, as the disease returned, Mr. Ernie removed it a second time, together with the greater part of the scapula. The disease, however, being of a malignant character, again returned, and proved fatal. Several cases of this description have been lately met with in the hospitals of this metropolis. One was in the South London Hospital, under Mr. Lister. I found it another in the Westminster Hospital.

Removal of the whole of the skull, with the exception of its base, was performed by M. Simon. The particulars are related in M. Malgaigne's Manual. Many arteries required ligation, and among them, the posterior tibial. The internal pudic nerve was also divided. As the skin was slightly affected, the cautery was applied to it. In two months the wound was healed, and

as fear the patient could bear nearly as well as this leg as on the other.

In the articles *Amputation*, and *Gnathic Wounds*, I have noticed the excision of the upper head of the humerus; and in *thickened Anchylosis* an account is given of Barton's section of the head end of the femur, an operation to which an allusion is made in the writings of C. White, of Manchester, and which has been performed by Sir Benjamin Brodie, Mr. Anthony White, and in Germany by Oppenheim. Sir Benjamin Brodie lately informed me that his patient died some time afterward of phthisis. I believe the case was one in which it was ascertained that the disease was restricted to the head of the femur. My friend, Mr. Anthony White, has favoured me with the following particulars of the case in which he performed the operation. John West, a twin of delicate make, was born and reared in Westminster. When between five and five years old, he suffered from scrofulous inflammation in the left hip-joint, which passed through the stages of enlargement, calcification, and subsequent perforation, and the femur was finally lodged in a very high position, on the dorsum of the ilium. About three years subsequent to the commencement of the disease, and when he was about eight years old, I first saw him. He was much emaciated; several abscesses had formed during this period around and over the diseased structure, leaving many fistulous openings, through which the pus-sometimes detected the surface of the displaced bone to be in a state of caries, and several small cysts had excoriated from the ilium, ischium, and on perine, over which bones abscesses had formed. In the progress of the disease, the knee of the affected limb had become inverted, and firmly imbedded on the lower and inner part of the opposite thigh, from which position it could not be removed, and every attempt to do so was accompanied with exquisite pain. All further attempts, therefore, were abandoned, and the limb left undisturbed. He had now been nearly three years on the opposite side, with the body considerably incurved, and without the power of changing his position. A profuse and debilitating discharge was constantly issuing from the numerous openings leading to the carious surface of the displaced bone. In other respects, the health of the boy was tolerably good. Reflecting on this poor boy's case, it was evident that, unless the knee could be removed from its firm lodgment on the opposite thigh, he must remain in the position above described during the remainder of his life, and this could only be effected by removing the upper portion of the femur, which, from its fitting mobility, induced the belief that a firm union was taking place between its under surface and that of the ilium, with which it had been long in contact, and the form of which was very apparent under the thin integuments with which it was covered. Considering, also, that, as an entire destruction of every bone which forms a healthy joint had taken place, no danger could be reasonably entertained from meddling with parts in their existing condition, and attempting the removal of the head of the displaced bone; and, further, that the strength of the boy, from the profuse discharge kept up by the caries of the bone, was never likely to be restored, I was induced, after mature reflection, to propose an operation for the removal of the upper part of the femur as far as it should be found in a state of caries, which, from examination with the probe,

appeared to extend probably a little lower than the great trochanter. If this could be accomplished, it would set free the lower portion of the bone imbedded on the opposite thigh, and enable me to draw outward the whole limb, and possibly place the boy in a condition rapidly reconcilable with those cases, where a similar disease had occurred, and in which a compensatory joint is formed, on which locomotion is effected with or without the aid of a crutch. I proposed to divide the integuments covering the bone, beginning above its head, which was easily detected, and carry it downward in the centre as far as might be found necessary, and separate the soft parts from the shaft of the bone towards either side. I then proposed to divide the bone at the lowest exposed part with a small saw, and to elevate it with a lever from the dorsum of the ilium. I hoped that the wound would heal over the divided end of the bone, which (now being set free) might be brought into a straight line, and which motion would incline deeply into the wound the end of the divided bone. The wound itself was to be treated as a common incision with adhesive plaster and bandages, and need quietude. My colleague, the late Mr. Mead, saw the case, concurred in the proposition, and offered to be my assistant. The late Mr. William Smith, member for Norwich, and to whom the mother of the boy was well known, informed the late Sir R. Home of the proposed operation. The boy, at his request, was conveyed to St. George's Hospital, and, after an examination of the case with his colleagues, a written document, signed by him and them, was given to the mother of the boy, declaring that the contemplated operation would not only be useless, but impracticable, and more likely, if attempted, to attend with loss of life. I was not present at this consultation, and only knew of it by being shown this document or posted by the boy's mother. Of course, with such a published declaration, I abandoned the case altogether. After the lapse of some months, Mr. Travers, while attending at Mr. Smith's house in the city, to which the boy West had been removed with his mother, was requested to look at him; and being told of the proposed operation by the mother, who was an exceedingly intelligent person, at once saw and understood the principles and plan of the proposition. He subsequently wrote me a note, expressing his entire concurrence in the measure, and kindly offered to assist me in the operation, notwithstanding the formidable protest which had been issued shortly before. Glad of the concurrence of so distinguished an individual, and my own opinion as to its practicability being unchanged, I gladly accepted of the offer. A lodging in Westminster was procured for the boy and his mother. We met in consultation, and an early day was fixed for the operation.

In April, 1821, we met; and the boy being placed on a table of convenient height, I proceeded to divide the integuments covering the bone, carrying the incision from an inch above the head, directly along the middle line of the bone, about two inches below the greater trochanter. This was completed at one incision down to the surface of the bone. The integuments were dissected inward and outward, thus leaving the bone entirely bare a little lower down than the lesser trochanter, which was distinctly visible. A spatula was now placed under that part of the bone which was intended to be sawn through, so as to protect the structures under-

mouth. This was readily accomplished. A small-er spatula was then introduced into the space made by the saw, and used as a lever to raise the bone, which, with a little dissection, was removed from the dorsum of the ilium. No vestige of the abscessum remained, neither was any mass of the ilium discovered. The thigh was now readily brought into a straight line, and the knee flexed into its position on the thigh. The wound was closed by adhesive plaster, and no portion of the bone was left exposed. Splints and an eighteen-tailed bandage were applied, and the limb placed in the straight position. The boy bore the operation well, and not more than two ounces of blood were lost. The head, neck, and trochanters were very apparent, the caries being superficial, and not extending farther than the lower one. The case presented very favourably, and in a few weeks every sinus opening had healed, and also the incision made in the integuments. The patient rapidly acquired strength and flesh. At the end of two months I began to examine the parts, to ascertain if they had formed any attachment to the surrounding structures; and, on attempting to move the limb in different directions, I discovered that the boy himself had the power of raising the thigh upward, which power gradually increased, and, finally, a very extensive motion was accomplished by the spontaneous action of the muscles. I now proceeded to examine whether he could bear pressure upon the foot without inconvenience, which was the case at the expiration of about four months from the time of the operation. He was put on crutches, and in a very short time could bear considerable pressure on the foot, and at the end of a year he could walk on a high stump without his crutches. Finally, it was clearly ascertained that a new and useful joint had been formed, the boy being enabled to walk several miles without the aid of a crutch or stick. He acquired great latitude of motion, except in rotating the thigh outward and separating the thigh laterally outward. He was appointed to a lady's schoolmaster, and two years after the operation he became phthisical, and died of diseased lungs in the West-minster Hospital. The limb was removed with half the pelvis, and is in the possession of the Royal College of Surgeons; but the parts have not yet been examined, in order to ascertain the changes which had so usefully been employed in giving almost a perfect joint as a compensation for the original. The shaft of the femur appeared to have lost the power of further elongation; for, on disjunct-admersionment during the life of the patient, it was discovered not to have increased in length. Probably the fact is not generally known that bones do not increase in length after the ossification of their heads."

REMOVAL OF THE UPPER JAW-BONE.

In the article *Atrum*, certain stages of disease of this cavity are noticed, in which the only chance of cure depends upon the entire removal of the upper jaw-bone itself. I allude to osteo-sarcomatous fibrosis, and other tumours, which originate within the atrium, and by enlargement produce such an impediment of, and pressure upon the surrounding organs and textures, as must ultimately prove fatal unless a bold attempt be made to extirpate every part of the osseous structure, serving as a place of attachment to the swelling. Merely entering the alveolus and front of the nostril, and then attacking the tumour with the knife, cautery, or caustic, gener-

ally fails. Baron Dupuytren was led to suppose that by the excision of the upper jaw-bone an total extirpation might be performed with a successful result. He was induced to form this opinion from the consideration of the anastomosis on record, where the patients recovered after most severe mechanical injuries of the face and nostrils, occasioning the destruction of the bone. Camper mentions a case in which the whole of the bone came away in consequence of falling, and the patient was cured. Assuredly it would, indeed, to have actually removed the upper jaw-bone a tumour of the face as long as 10 1/2. Billroth and Deschamps also anticipated Dupuytren in the belief that the upper jaw-bone could be successfully extirpated, though they never undertook the operation themselves. The relations of the Family of Medicine at Paris from that Dupuytren removed, at all events, the greater part of the bone in 1824; but, as M. Pilon and Genoul contend, probably not the whole of it. M. Velpeau states that, in 1824, Mr. Roux, of New-York, removed both upper jaw-bones as far back as the pyriform process, and this without making scarcely any incision through the lip. (*New York Med.*, t. 1, p. 540.) In 1828, Mr. Lister also advocated the removal of the whole of the upper jaw-bone, and he performed the operation with success in 1825, 1828, and 1830. In May, 1837, M. Genoul, surgeon to the Hôtel Dieu at Lyons, removed every part of this bone, together with the whole of the palate bone, on account of a fibro-cartilaginous tumour, and the patient got completely well. (*New Velpeau, Ann. Elém. Méd. Opér.*, t. 1, p. 247; *St. Simon, Lect. Chir. sur quelques Maladies Orues de la Bouche Malheureuse*, &c., p. 18, 8vo, Paris, 1831.)

In this work M. Genoul states, that several years previously he had known patients die of very tedious operations undertaken for the removal of cancerous and other tumours of the atrium. Reflecting on the fate of these unfortunate individuals, he was led to conclude that others labouring under similar diseases might be cured by an operation which consisted in freely dividing the atrium and upper jaw-bone, so as to be able to divide the osseous parts instead of meddling with the diseased mass, and of searching for the precise limits of the disease in the midst of blood and the remains of the affected textures. In short, he was induced to think that the same principle should be acted upon in this operation as is followed in others undertaken for the extirpation of cancerous tumours in general.

If the face of the skeleton be examined, it will be seen that the upper maxillary bone is fixed to the others only at three principal points: 1. By means of its nasal process, and at its connection with the os trigonum and ethmoid bone. 2. By means of the alveolar process of the maxilla bone as far as the alveolo-maxillary foramen. 3. By means of the connection of the upper jaw-bone to the fellow, and to the palate bone. There is, indeed, a point of contact behind with the pyriform process and palate bone; but this point gives way on depressing the upper jaw-bone to waste the mouth. In attacking these difficult points, no large vessel is injured, the trunk of the internal maxillary artery generally escapes, and, if wounded, may be readily tied, as was exemplified in the removal of the whole of the upper maxillary bone, performed by Mr. Lister at the North London Hospital on the 27th February, 1836. If the hæmorrhage during the oper-

sion were to be greater than calculated upon, the carotid artery might be compressed against the transverse processes of the cervical vertebrae. As for nerves, the only one of consequence necessarily divided is the superior maxillary; but it may be easily cut through before the bone is displaced, and then the laceration is healed, if judged advisable. This proceeding is strongly advocated by M. Gosselin; but in the operations which I have seen performed, no preliminary division of the trunk of this nerve was practised, yet no ill consequences were the result.

The patient should be seated in a chair, with his head inclined backward, and supported on the breast of an assistant. One of the incision teeth is to be extracted at the place where the division of the bone is to be effected below. An incision is now to be made from the inner canthus of the eye down to the upper lip, which is to be cut through opposite the canine tooth; and the incision may then be made from a point five or six lines to the outer side of the external angle of the eye down to the termination of the fist. This will leave the parotid duct safe below it. The flap is next to be raised up as far as the lower border of the orbit. This plan is more simple and less disgusting than that of M. Gosselin, who, after the first incision has been made, makes a second from the level of the nostril to a point about four lines in front of the base of the ear; and then a third, extending from a point five or six lines behind the external angular process of the orbit down till it meets the termination of the second cut. The quadrilateral flap thus formed is then reflected on the forehead. M. Velpeau prefers no incision commencing at the commissure of the lips, and carried outward, and then upward towards the temporal fossa. This would not, however, expose the bone sufficiently for the section of its nasal process, for which purpose the perpendicular cut, from the inner canthus down to the upper lip, is very necessary. When the incision is large, the circular sweep of the knife, as advised by M. Velpeau, and long ago practised by surgeons in this country, has advantages. The bone having been denuded, the next step is to divide the connexion of the malar bone with the external angular process of the frontal, and immediately afterward the zygomatic process of the malar bone. These excisions are best accomplished with Liston's cutting forceps, which should have long powerful handles, a connexion fixed in the North London Hospital to answer better than jointed handles, which cannot be opened so wide, and have a tendency to slip off the bone instead of cutting it. The greater power with which they shut does not, therefore, seem to Mr. Liston to compensate for the inconvenience referred to. At all events, any additional power required can be obtained by simply lengthening the handles.

The next thing is to divide the nasal process of the superior maxillary bone, and the connexion of the latter bone with the os unguis and os planum. For this purpose, one blade of the forceps is put within the orbit, the other within the nose, and the section accomplished.

This having been effected, and a cut made under the lower part of the palaty, the upper jaw bone is divided with the same instrument at the place where the incisor tooth was extracted, together with the palatine process and palatobone at the symphysis.

The bone being next pressed downward, the slight connexion with the pterygoid process

through the antrum of the palate-bone given way, when the upper jaw-bone, including the whole of the antrum and disease occupying it, is easily dissected out. The flap is brought down, and the wounds united with the twisted suture, aided with narrow strips of adhesive plaster. Mr. Liston prefers, as less irritating, strips of silk smeared with a solution of ergoline in brandy. These strips he does not usually remove till the wound is healed. The straight steel needles which he employs for the twisted suture, and the eye-nails of which are tipped with red sealing-wax, and the points cut off with glass directly after their introduction, are removed within the first forty-eight hours, leaving the many-twisted silk to come away as soon as it loosens.

The following is Mr. Liston's description of the operation: To expose the bone, the cheek is divided from the angle of the mouth to the origin of the nose, and a second incision made from the inner canthus to the edge of the upper lip, near the nasal line, detaching the skin of the nose from the maxillary bone. The flap of the cheek thus formed is dissected up, and the nasal process of the maxillary bone and the body of the os maxila are divided with a saw or with strong cutting pliers. An incision having been made through the covering of the hard palate, near the nasal line, a small converging saw is applied to the bone, and the alveolar process is cut through with the glass, after extraction of the middle and lateral incisors. The bone is then rolled downward and forward, and its remaining adhesions severed by means of the lancet or pliers. During the progress of the operation, the six branches of the facial and temporal arteries are interrupted by ligature or pressure, and the violence of the hemorrhage is moderated by pressure on the carotids. After removal of the bone, the deep vessels, branches of the internal maxillary, are secured either by ligature, or by firm pressure with clamps or dooms of lint. The facial flap is retracted, brought together over the clamps, by which the cavity is filled, and united by interrupted or continuous suture. (See Liston's *Essay*, part ii, p. 158.)

In the examples of this operation which I have seen, any preliminary ligature of the common carotid artery would have been totally unnecessary. In one instance the internal maxillary was cut, but secured with the greatest facility. In a case operated upon by Mr. Liston in the North London Hospital, not a single ligature was necessary.

It is an important object to prevent, as much as possible, the blood from flowing towards the throat in the early part of the operation; hence the advantage of the sitting posture, and of Gosselin's plan of beginning with the division of the cheek-bone of the nose, before the nasal process of the upper jaw-bone itself is attacked.

RESECTION OF LOWER JAW-BONE.

The practicability of this operation was long ago evident enough, from cases in which the greater part of the bone had been torn away by gunshot injuries, or where it had exfoliated from necrosis. Borel relates an instance in which it was taken away by machinery, and Wepfer quotes a case where it was amputated in his time. Mr. Anthony White, surgeon to the Westminster Hospital, removed a considerable portion of the bone for an osteo-doma many years ago. Unfortunately, the case was not pub-

ished, so that the revival and execution of the operation are generally referred to Dupuytren, who in 1812 performed his earliest extension of the body of the lower jaw-bone. The parts removed weighed a pound and a half; the bone was affected with exostoses, caries, and necrosis, situated in several places, and covered with a hard fibrous crust. The patient recovered, and was in perfect health twenty-one years after the operation. (*Dupuytren, Clin. Chir.*, t. iv., p. 628.)

Subsequently to the year 1812, the operation has been frequently repeated by Dupuytren, Dr. Mott, Richardson, Lallemand, Delpech, Roux, Courch, Martin, Geely, Magnan, Cloquet, Wainman, Lichane, Warren, Gossard, Gräfe, Wallner, Wagner, Ranselöph, Liston, Lawrence, P. Crumpton, Velpeau, &c. By McClellan, Walker, and Gräfe, nearly the whole of the bone has been taken away. In many other operators, disarticulation has been performed at one of the condyles. (See *Cham. in Dublin Hospital Reports*, vol. iv., p. 13; *Lancet's Flou.*, part ii., &c.)

The method of performing the operation varies according to the extent of the disease. To expose the tumour, and allow the body to be readily divided, there must necessarily be a free division of the soft parts. Previously, also, to exposing upon the plan of operation, the extent of the disease must be correctly ascertained. (See *Gossard's Flou.*, part ii., p. 224.) When only the central portion of the body of the bone was to be removed, the following was Dupuytren's plan: the patient is seated, and his head held steady against the breast of an assistant, who is to stand behind him, and, if necessary, make pressure on the facial arteries. The surgeon, standing in front of the patient and on his right side, is to take hold of the right portion of the lower jaw with his left hand, while an assistant takes hold of the left portion. In this way the jaw is rendered tense, and separated from the other. With a common scalpel an incision is then made completely through it, from above downward to the base of the jaw. The next thing is to extend the wound through the skin and cellular tissue from this point down to the prominence of the os hyoides. These two flaps are produced, each of which is to be dissected up as far as the extent of the disease requires, while the knife kept close to the bone, so that the facial arteries may not be wounded. The exact places having been ascertained to which the saw is to be applied, a notch on each side must be extracted. The operator then taking a fine malleocephal saw, or one of Hey's, goes behind the patient, in which position the saw can be employed without any risk of its extremity being pushed against the palate. It requires, the lower and upper lip may be protruded within piece of pasteboard. But, according to my observations, the best plan is only to make a groove, or partial division of the bone with the saw, and then to complete the section on each side with the riving pliers, which expedite the business very considerably, and with no risk of injury to the contiguous parts. The bone having been cut through on each side, the surgeon takes hold of the portion about to be removed with his left hand, and, while it is retained forward, he introduces a straight bistoury from below upward close behind it, and detaches it from the soft parts to the right and left, keeping the edge close to the bone. An assistant takes care to keep the bistoury on the way with a spatula or the handle of a director. The vessels are now secured, the ends

of the bone approximated to one another, and the flaps of skin united with sutures; care being taken to leave a small portion of the wound open below for the insertion of a bit of charcoal, and as an outlet for the discharge at the time of matter being formed.

If the portion of bone to be taken away was so extensive as to require the removal of a part of the integuments, Dupuytren made two incisions, one in each side of the lip, which were extended down so as to meet the os hyoides, and from together rose in the shape of a V. When a perpendicular cut will not suffice, an extension of the extent of the disease, it may be converted into a cruciate wound by making an incision along the base of the jaw.

One danger attending this operation is the retroversion of the tongue into the pharynx as soon as the attachments of the genio-gloss muscles behind the symphysis have been cut. In this state the tongue presses the epiglottis against the glottis, and the patient is in imminent peril of suffocation. Indeed, in one case, M. Lallemand would have lost his patient had he not instantly performed tracheotomy. Hence Delpech, before he divided the muscular connections of the tongue behind the symphysis, used to secure the extremity with a elastic bandage, which was then intrusted to an assistant, and afterwards, in applying the scissors, he passed the thumb of one of them through the median of the finger and the skin together; if the interrupted suture were employed, an assisting the tracheal suture to be performed, the ends of the thread, passed through the incision, were twisted around the pins. In one case Delpech introduced a piece of gold wire through the apex of the scissor, and fastened it to the cutaneous teeth. The wire soon cut its way out, leaving a sufficient adhesion. In few instances, the circumstances of the disease may be such as to make it necessary to remove only a portion of the depth of the bone.

As the retroversion of the tongue, though not constant, is always a possible event, I consent with Malgaigne (*Mé. de Méd. Oper.*, p. 259) in the preference of extending to the skin directed on this subject by Delpech, of close taking care not to cut through the tendons of the genio-gloss muscles until the possible displacement of the tongue has been guarded against.

In the extension of the whole of the horizontal portion of the lower jaw-bone, one plan consists in making an incision along its base, and extending it a line or two beyond its angles. A large flap is thus dissected up, and turned over the face. The bone is sawn on each side beyond the limits of the disease, and then detached from the soft parts which are connected with it behind with the precautions, and according to the direction above particularized.

If the disease were to extend high up in the right, an incision should be made along the posterior edge of each ramus so as to meet the extremities of the first wound.

Another method, described by M. Malgaigne, is easier than the foregoing. After the horizontal incision has been made, a perpendicular one is made completely through the lower lip, and carried down to the middle line till it meets the horizontal wound. Both the lateral flaps are then dissected up.

In the extension of one half of the horizontal portion several methods are adopted. In one, performed by several British surgeons, and also by J.

Chopart, a horizontal incision is begun at the commissure of the lip, and terminates at the distance of one or two lines beyond the angle of the jaw. To this first incision are added two vertical ones: one descending from the border of the lip to the base of the bone; the other, taking a parallel course, descends behind the massa to a point a few lines below the angle. The flap is dissected from above downward; the soft parts are most detached from the inner surface of the jaw, and, lastly, the bone is sawn through. In the latter proceeding I particularly recommend Hey's saw, or a small rectangular one, forming a groove in the bone, which can then be divided with the cutting plane at one stroke, as practiced by Mr. Liston, and always demonstrated by me in the Lectures on Operations at the London University.

Mr. Liston has likewise expressed himself as follows in favour of one method, in which the flap is made from above downward: "The cheek may be divided (says he) by passing through it a large narrow bistoury close to the anterior edge of the masseter muscle, and carrying the instrument forward, and through at the angle of the mouth. From each extremity of this incision another is made downward, the anterior one inclining forward, the other backward. By refection of the flap thus formed, the bone is exposed more easily, rapidly, and perfectly than by the former mode of incision, in which the flap is made by a semicircular incision along the base of the jaw." (*See Liston's Elem.*, part II., p. 224.)

In the plan adopted by Dr. Moir, at New-York, two flaps are formed. A curved incision is made, with its convexity downward, from a point in front of the ear, and on a level with the cyclops, to the trinity of the chin below the commissure of the lip. The upper flap is raised and reflected on the face. A second incision, descending from the upper end of the first to the angle of the jaw, enables the surgeon to form a lower flap. The bone is sawn through, first in front, and then behind, as high up as the circumstances of the case require. If above a certain point, Dr. Moir recommends the inferior maxillary nerve to be cut through before the bone is drawn outward, and the lingual branch of the fifth pair to be carefully avoided.

A third method, which has the names of Cusack, Liston, Liston, Malgaigne, &c., in its favour, consists in making, first, a vertical incision through the lip down to a point below the chin, and then a horizontal cut, extending from the first along the base of the jaw to two lines beyond its angle. The flap is then dissected off the hardest, in the direction from below upward, and reflected on the face. The bone is then sawn through in front and behind, and the flap united with sutures. I am of opinion with M. Malgaigne, that this plan is more simple than the others; no ligament of any value is likely to follow it, and the scar will produce but slight disfigurement. I recommend, however, the front portion of the bone to be divided before the posterior part of it, so facilitating the safe detachment of the mylohyoid and other parts connected with its inner surface.

One method, described by Mr. Liston, is a modification of the foregoing: "If the tumour is included between the lateral maxillary tooth and last molar, in the same side these teeth must be extracted to permit division at these points. A semicircular incision may then be made along the base of the jaw, the bases of the incision pointing up-

ward, and passing over the spaces which were occupied by the extracted teeth. The flap is dissected up, and the membrane of the cheek divided along the line of the incision. The bistoury is then carried along the inside of the bone, so as to divide the membrane of the mouth, and separate the attachments of the muscles. The tongue is pushed aside, and a copper spoon placed under the jaw at the part to be divided, in order that the soft parts may not be injured during the sawing. A small narrow saw, or one commonly known by the name of Hey's, is applied to the bone at the points where the teeth were extracted, and by a few motions of this instrument a notch is made of no great depth; a pair of strong pulling-pliers are placed in the track, and by their division of the bone is accomplished with great ease and much more rapidly than if the use of the saw had been continued. The pliers should be strong in every point, and the handles long, to afford the advantage of a powerful lever." The chin-ear, he says, is not to be depended upon, and is shown in its operation. (*See Liston's Elem.*, part II., p. 224.)

A fourth plan, described by M. Malgaigne, may be applicable where the disease extends more in the direction backward than forward. In such a case, perhaps, it may be sufficient to make a semicircular incision along the posterior border of the ramus and the base of the bone, from the ear to the chin. Thus only one flap would be formed, and no excision would be made on the face.

M. Malgaigne says it down as a maxim, that, in making the flaps in any of these operations, the skin and cutaneous tissues should alone be divided; and that the remainder should be cut through, and removed at the same height as the bone itself.

The facial artery is readily secured. All those operators who have had recourse to the ligation of the carotid artery as a preliminary measure, have subjected their patients to a very needless proceeding.

Even in the course of per half the lower jaw, as its articulation with the temporal bone, the ligation of the carotid artery is quite uncalled for. Our plan consists in making an incision along the base of the jaw; a second cut is then made perpendicularly through the lower lip down to the first; and a third begins at the epiglottis, and extends behind the ramus. The flap is raised, and the free part of the bone sawn through. The soft parts are then detached from its inner surface, and the tendinous attachment of the temporal muscle to the coronoid process cut through from within outward. Lastly, the disarticulation of the condyle is effected: for this purpose, the external lateral ligament should first be divided; and, while the bone is depressed and twisted, in order to render the capsular ligament tense, the lower part may either be cut through with scissors, as recommended by M. Malgaigne, and then the corresponding history used, or it may be divided at once, together with the external pterygoid muscle, by means of the probe-pointed bistoury kept close to the highest part of the inner side of the condyle, so as to leave the inferior maxillary artery safe on the inner side of the neck of the bone. A green end of the safety of this operation will depend upon the edge of the knife being kept close to the inner surface of the bone, so that the ligament branch of the fifth nerve may be left unimpaired, and, upon attention being paid to the directions given for the disarticulation.

tion, which, after the insertion of the temporal muscle has been divided, is greatly facilitated by depressing the anterior part of the bone forcibly, and twisting the condyle inward. The fracture will be chiefly from the facial, dental, and branches of the temporal and internal maxillary arteries.

Instead of making the flap exactly in the manner above described, I prefer making, first, the anterior perpendicular incision, and then another, beginning a little way in front of the lobe of the ear, extending down along the posterior border of the tragus, and then forward along the tip of the base till it meets the lower termination of the first wound. This is most simple, and enables the surgeon to get more readily at the external lateral ligament.

In the terrific operation of extirpating the whole of the lower jaw-bone, the incision should extend from a point a few lines in front of the lobe of one ear, down the posterior edge of the tragus along the whole base, then one angle to the other, and then up to a point a few lines in front of the lobe of the other ear. Care having been taken to prevent introduction of the tongue, and the front portion of the flap raised, the soft parts behind the symphysis should be cut, and the bone saved in this situation. Then the use of the vast flap is to be raised on each side, and each half of the bone to be removed according to the foregoing directions.

BONES, PATHOLOGY OF.

As a living texture, that of the bones is subject to many of the diseases which affect other parts endowed with vitality, and in which the functions of circulation, assimilation, absorption, and nutrition are essentially going on. Thus it is liable to atrophy, hypertrophy, inflammation, suppuration, a change resembling tubercles, and another like modification of other parts. The nerves, it is said, have never been demonstrated in the osseous texture; yet, if it be the end of pain, our judgment must infer the existence of what may not be discernible by the eye. M. Sanson very aptly compares the organization of bone to something between that of an organic and that of an inorganic body, its vitality being necessarily obscure, and corresponding to its constituent elements. The organic actions, when implied, to be carried on in it with greater difficulty, the more the earthy matter in it predominates over the animal part. Thus, in children, irritation, inflammation, and every action in the osseous texture are quicker than in old persons, because the bones in early life contain a greater proportion of animal matter than at a later period, when the phosphate of lime is more abundant. However, even in children, and still more conspicuously in adults and old persons, the diseases of the bones are generally marked by a slowness of character which has attracted the notice of all pathologists. Many weeks are required for the completion of a provisional callus, and months a twelvemonth for that of a definite one; while a few days, and often a few hours, will suffice for the union of the wound of the soft parts. In consequence, also, of the inferior, or inconsiderable extension of the bones with the nervous system, they frequently appear to inflame and undergo disease, without involving the rest of the system in any sympathetic disturbance, till the irritative is propagated to the surrounding parts, or suppuration comes on. As M. Sanson observes, a necessary consequence of

this fact is, that therapeutic means, even those of the most energetic kind, frequently have but little power over affections of the osseous tissue, and if they prove effectual, it is not till after a long perseverance with them. (See *Sanson's Diss. de Med. et de Chir. Phys.*, t. XII, p. 308.) See ANKYLOSIS, CARIES, CARIES, ENOSTOMA, ENOSTOMA, JOINTS, MALIGNANT, NOSTOMA, OSTEO-SARCOMA, OSTIUM, PLEURISITIS, RHEUMATISM, SCURVY, STYRIA, TUBERCLES, TUBERCULAR DISEASE, AND VITRIFICATION.—C.]

BRONCE, ATROPHY OF. One of the forms of Atrophy of Bone, by Thomas Robert Bell. Local atrophy is generally the result of pressure or friction, as experienced in the effects of tumours and other tumours on the skin, and in the change taking place in the size and shape of the head of the maloccluded humerus, if not is altered. Of such alterations there are some excellent specimens in the University College Museum. Mr. Curling notices also the local atrophy of bone from mechanical injury, and refers to the two thigh-bones figured by Cheselden in his *Anatomical Tables*, taken from the body of a soldier who had been shot in the right groin, and died soon afterwards of dropsy. The right femur is mentioned as much wasted, and to have been less than half the weight of the other.

The author likewise alludes to the atrophy of bones consequent to a suspension of their functions, and to that induced by deprivation of the nervous influence, as sometimes attended in cases of injury of the spinal chord. Mr. Curling adduces instances of these facts, and refers to a case recorded by Mr. Travers, in which the union of a fractured leg, that was paralyzed from a fracture of the lumbar vertebra, failed to proceed, while a broken humerus in the same subject united perfectly in the usual period. (*On Constitutional Lesions*, vol. II, p. 436.)

Although the fracture of the femoral artery is a fracture of the leg complicated with hemorrhage is well known not to interfere with the nutrition of the bone or the union of the fracture (see *Fractures and Trauma*, p. 500, vol. II) appears from Mr. Curling's investigations that, if the supply of blood to a bone by its natural artery be obstructed, a species of atrophy will come. Thus, in the thigh-bone, if fracture below the entrance of this artery, the walls of the portion of such bone below that point will be found thinned, and the cancelli expanded, such changes, however, is not observed in bones recently fractured, nor in those long united, nor in bones fractured during the period of growth. Mr. Curling correlates with some interesting examples on fractures of the neck of the femur. (See *Med. Chir. Trans.*, vol. XXI.—C.)

BRONCHOCELE. Scarpa believed that the thyroid gland was never primarily affected with true scirrhus, maintaining that the disease was always consecutive to cancer, or scirrhus of the lungs, oesophagus, parathyroid or sublingual gland. Dr. Sæverus relates a case, however, proving that on this point Scarpa was incorrect; and he also details an instance of fibrous hematomas of the thyroid gland. Of this last disease there are at least two specimens in the Museum of University College.

Besides the form of goitre already named, there is another, sometimes termed *acromioid*, and consisting of an extraordinary development of the thyroid arteries and their branches. Every point of the tumour has a strong pulsation, not, however, like that of an aneurism, but giving a

operation and the blood was flowing very rapidly into numerous vessels, with an obscure hissing noise or rattling murmur, which is most distinct over the thyroid trunks. I think a case of this description was once shown to me by Mr. Fisher. In two cases recorded by Dr. Sarsin, the tumours had existed many years, and began during the efforts of parturition.

Notwithstanding the numerous cures of bronchitis accomplished by means of iodine, the plan fails in many instances. As Dupuytren observes, the disease depends on different causes sometimes it is a simple hypertrophy, sometimes a scirrhous degeneration; and on other occasions it is composed of cysts filled with matter of differing kinds. Iodine cannot however equally be so many affections of diverse character. (*Chronic Obs.* t. iv. p. 467.) According to Dr. Stiebel, iodine is chiefly useful in the hypertrophic and scirrhous forms; less so in the lym-

phatic; and perfectly ineffectual against small, isolated, solid nodules. The best mode of using iodine seems to Dr. Sarsin to be friction, with an ointment of hyaloidine of potato, continued from time to several months.

When a tumor was passed through the thyroid gland, Dupuytren already noticed a copious discharge of venous blood; but he found it soon stop on securing the patient to make full inspirations, and applying cold water and moderate pressure. (*See Chronic Obs.* t. iv. p. 470.) Dupuytren would not have the tumor looked upon as capable of causing every bronchitis. Of course, it will produce no fundamental change in the scirrhous degeneration of the thyroid gland; but, in cases of hypertrophy, cysts, and hydatids, where iodine and other specifics frequently fail, the disease will be more likely to yield to the action. (*Ibid.* p. 471.)—C.]

C.

[CÆSAREAN SECTION. According to Bayle, August Cæsar's mother, was lying at the period when that source decided Spring, so that, if he were taken out of the womb by this proceeding, the life of the mother was saved. Although the etymology and free practice of the Cæsar operation are points involved in controversy, its great antiquity is generally admitted. Mr. Cæsar has lately adverted to some recent instances in which the Cæsar operation was performed "in a majority of the instances which may demand it: he across pelvis, tumours in the uterus or vagina, extra uterine conception, rupture of the uterus, and sudden death from apoplexy and other causes. The operation (says he) has also been performed, and with success, in the leading countries of the world. In England we have a single and most critical example of its success by Mr. Knowles, of Birmingham; and in America, Professor Gibson has been the first to save the life of both patient and child by this intrepid proceeding. The most frequent examples are to be found in the publications of France and Germany; and I have grounds for stating that on some occasions the operation has been resorted to where there seemed to be danger by a hope of any good result, or determined on when not absolutely called for, or performed and more often where obviously applicable, not only because calculated to avoid protracted suffering, but to afford a chance of saving life. Bayle in the æternæ ariston calls for ventro-section, Among the numerous cases of this accident, no less than thirty-five, related by Dr. Collins, there is scarcely one in which the operation could have been undertaken with propriety. The recovery of two patients after rupture of the uterus in Dr. Collins's practice, and under the most unfavourable conditions, should inspire the less anxious of the departing on the occurrence of so formidable an accident." (*See J. G. Owen in Pract. Med. and Surg. Trans.* vol. v.)

From a statement made by Blandineau, it appears that the Cæsar operation had been performed twenty-four times with success between the year 1750 and the beginning of the present century; and according to M. Velpeau, even without including Lapeyrol's cases, which

are acceptable, it has also been practised with a favourable result twice at Nantes, by Baccin, on the same woman; once at Aix, by M. Le Masson; once by M. Ponsard, at Marseilles; once at Delfin, by Vonderfuer, in 1823; once in May, 1825, in the Hospital of Florence; twice by Schæffer; once by Hipp; once by Græfe; once by Burns; and more more, quite recently, in the colonies. Let not practitioners, however, underrate the true danger of the operation; for, as M. Velpeau justly observes, no doubt every successful case has been brought before the public, while many unsuccessful ones have been kept out of view. His belief is, that at least half of the operations here had a fatal termination. (*See Nouv. Élév. de Méd. Opér.* t. iii. p. 677.)

Rich, a surgeon in Upper Silesia, performed the Cæsar operation successfully in a case of extra-uterine pregnancy of some years standing, during which period the woman became pregnant in the ordinary way, and was safely delivered. (*See Græfe and Walther's Journ.* part vi., vol. vi.) The particulars, which are well deserving of the attention of obstetric practitioners, may also be found in one of our own periodicals. (*See Edinb. Med. and Surg. Journ.* vol. xliii. p. 429.)—C.]

[CÆSAREAN OPERATION.

When the former edition of this Dictionary was published, it was correctly stated that in England the operation had never been successful, though it had been performed thirty times. The only instance of its performance in America at that period was the case reported by Dr. Richmond, of Newforn, Ohio, in which the mother was saved. Since then, however, Professor Gibson has been the instrument of conferring celestial favour upon American surgery by the successful performance of this splendid operation, and repeating it about two and a half years afterward upon the same patient, and in both instances he has completed his triumph by saving both mother and child, a result which has never been attained before in the United States. Indeed, there is not a single instance of a similar result in Great Britain, and that by Mr. Knowles, of Birmingham, recently reported.

The circumstances of this intrepid proceeding

of Professor Gibson, which is an honour to his surgical science and skill, together with the history of each operation and its results, will be found supplied with great particularity in his late edition of the *Lectures on Surgery*. For the purpose of discriminating this operation from gemmation, which is sometimes necessary for removing an extra-uterine foetus, he demonstrates it hysterotomy, or Cæsarean section. The extraordinary interest which these operations possess in themselves, especially in view of their being performed upon the same woman, and often crowned with complete success, entitle them to a place here.

The lady who was the subject of these operations was found, on her first labour, to have a deformed pelvis, the antero-posterior diameter not exceeding two inches. The constitution stimulated in the case was swayed by the adverse judgment of Dr. Physick, and other distinguished surgeons, which was adverse to the Cæsarean section; and it was decided to remove the child by epiotomy, which was accomplished by Dr. Meigs. This was in May, 1831; and in June, 1832, it became necessary for the same gentleman to repeat this operation for the removal of a second child, it being, of course, impossible to deliver per vias naturales, and the patient at the time refusing to submit to the Cæsarean section, though advised thereof.

In 1834 this lady became pregnant with her third child, and by the justifiable advice of her physician, Dr. Natchez, she consented to risk her own life in the hope of saving that of her offspring. On the 25th of March, 1834, her labour commenced; and, after the os uteri had dilated sufficiently to admit two or three fingers, the membranes containing water, Professor Gibson commenced the operation, in the presence of numerous professional friends, by making an incision from below the umbilicus nearly to the pubes, the skin being lifted up and held between the fingers of an assistant, and the back of the knife being towards the abdomen. The superficial fascia, the contents of the abdominal cavity, and the peritoneum being successively divided before cutting completely through the wall of the uterus, an unsuccessful attempt was made to rupture the membranes per vagina, on the failure of which the remaining fibres of the uterus were divided, and the membranes instantly opened by turning Cooper's trepan; the protruded hernia upward and downward the whole extent of the incision in the uterus, which measured six inches, the sides of the wound being held closely together, both to prevent protrusion of the intestines, and the escape of any portion of the waters into the bag of the peritoneum.

The position of the child was found to be the third breech presentation of Baudouin. The child was then removed by the feet, which was slowly performed, and proved to be a female of large size and healthy appearance. After suitable restorative, she breathed, and the cord being cut, the child lived. The placenta and membranes were then removed, and a finger passed from the cavity of the uterus through the dehiscence into the vagina. A slight protrusion of intestine occurred, but was soon restored; no fluid was permitted to enter the peritoneal sac, nor did any considerable hæmorrhage occur, so that no ligature was called for. The womb began to contract, and in a few seconds the extent of the incision had nearly contracted. The edges of the peritoneum, uterus, and integuments being

brought carefully together, three stout silk sutures were passed through the deep-seated sides of the interrupted line, an inch and a half apart, and with adhesive straps, a compress, and rube, the dressing was completed, the lower angle of the wound being left open to facilitate the discharges which might occur. The placenta being removed from the table to her bed with great care, was placed on her back, the uterus kept exposed, and she soon slept for several hours. No unpowered symptoms occurred, and on the 25th day the patient was able to sit up, the wound having healed kindly, and coagulation being nearly complete, and soon after was returned to her domestic household. The child was named Maria Casostema, and continues to thrive.

On the 6th of November, 1837, *Permetia* (this son was called to repeat this unusual proceeding on the same patient, she being in labour with her fourth child.) The different steps in the operation were nearly the same as in the former instance; and, although her recovery was slow, yet within three months she nearly recovered, the wound throughout having freely contracted. This child was found to be a male, and named Cesar Augustus. At his age (five years, 24th, 1843), this mother and her two children were in excellent health. The lady has not since become pregnant.

Professor Gibson has since confined upon himself, as well as upon American surgery, a number of which both may be found, among which Dr. Cooper has suitably noticed in his late edition. He accompanies it, however, with the acknowledgment of Mr. Knapp's case at Philadelphia, which met with success, and which was rendered necessary by a pelvic deformity requiring a similar resort.

Professor Gibson gives the following indications of the conditions and contraindications which it may become necessary to know the purposes of the abdomen, divide the peritoneum, and cut into the womb as in this operation: "Extraordinary distension of the uterus; of the ovaries and other viscera within its cavity; fissures of the instruments and vessels to be used by irregularity of course, or profusion of bleeding; of distensions of one or both thighs; of wounds of the uterus; of extraordinary size of the fetal viscera; of fetal immaturity; of lesions of the uterus; of preterm labour; of rupture of the uterus; of rupture of the ovary; of dissection of the uterus; of large tumor in the bladder; of strictures and obstructions in the vagina; of enlargement of os uteri; of extra-uterine conceptions; and other diseases, accidents, or malformations, or death of the mother." Happily, most of these emergencies rarely occur, and the propriety of the operation is often alone very questionable. So imperative a step should never be taken without grave deliberation and full consideration, and the difference should be well probably after surgeons have undertaken it, except when its necessity is decided on as called for in full view of all its dangers. In such a case, however, Dr. Gibson's caution will be courage + resolution when, as in his case, the duty of the surgeon becomes imperative.

We should never forget, however, that there have been cases in which the operation has been determined on, and yet, while the proceedings were making, the child has been born per vias naturales. And, moreover, women who have suffered the Cæsarean section as a parturient labour, and in one instance a repetition of a first

times, have nevertheless been delivered without it in a subsequent attachment.

It has been suggested whether, in cases of hopeless debility of the pelvis, the *Phlegon* tubes might not be devised in the progress of the Cancerous action, for the purpose of preventing the risk of a repetition of this inevitable operation. It would not increase the danger of the first, and would infallibly protect the patient from the hazard to life by a second place of the operation. With the consent of the patient and her husband, after explanation of its effect, there does not appear to be any moral or professional objection to adopting it. Such intelligent consent of the parties ought in all such cases to be granted, unless imperative in one sex to sterility, in the other as to be the result of surgery.

In the *Amer. Journ. of Med. Sciences* for 1855, Dr. Joseph G. Naamode, of Philadelphia, reports the last of Dr. Gibson's operations, which, indeed, was undertaken at his instance, accompanied by an elaborate and able paper on the general subject, to which the reader is referred for details and references of an critically practical character.

Dr. Valentine Mott, of New-York, has opened the abdomen for the removal of an enormous testis, which had been borne for one year and eleven months. The case was an unfortunate one, and terminated fatally.

Dr. Hoffman, of New-York, reports a case of Cancerous action performed by him on the person of a dwarfed forty-two years of age, who was in labor with her first child, and whose pelvis was as much contracted as to render embryotomy imperative. The case terminated favorably for the mother, but the child, which was also safely delivered, did not long survive its delivery. The case is reported at length in the *N. Y. Med. and Surg. Journ.* for 1859.—[Review.]

(CANCER.) Although the terms *cancer* and *carcinoma*, considered with reference to their etymology, seem distinctly to possess little commonization, the makers employ them with a far more precise and settled meaning than the ancient medicalists as they were by pathological analogy. Still our knowledge of cancer is not even now sufficiently advanced to enable us to answer conclusively various questions respecting it.—(See *Bégin in Dict. de Méd. et de Chir. Pratiques*, t. iv., p. 425.)

Frequently, a vast number of morbid alterations of structure, entirely different from one another, were denominated together under the name of cancer. The French academy to Laennec the merit of having first demonstrated the elementary texture of transudation, and thus freed the subject from a great deal of confusion. I believe, however, that Hume, Baillie, Hey, and Abernethy had all pointed out their observations on cancer when Laennec published. According to the latter distinguished pathologist, the human body is liable to two classes of accidental productions or new formations; to the first belong certain abnormal textures, to which some of the natural tissues are more or less analogous; in the second appertain other abnormal textures, which have nothing analogous to them in any of the primitive tissues of the body. Among the productions of the latter kind, Laennec arranged *adenoma*, *scirrhos*, the *encapsulated*, *carcinoma*, or (as we more frequently call it) the *solidary tumor*, and *melanoma*. Notwithstanding all or several of these abnormal elementary modifications of tissue may yet exist in tumors, various-

ly called *cancers*, yet, as M. Bégin well observes, and M. Laennec admits it himself, it is particularly to *scirrhos* and *carcinoma*, or *solidary formations*, that the term *cancer* is applied. In this article I shall confine my considerations to *scirrhos*, which French pathologists never regard as *cancerous*, but generally as a form of *scirrhous disease*. Neither shall I enter, at present, into the subject of *melanoma*, which, though sometimes regarded as a species of cancer, as he observes, by M. Alibert, who limits it *cancer vellosus* (*Ann. Medico-Chir.*, t. i., 1817, 406), will admit very advantageously of separate consideration. (See *Melanoma*.) According to Professor Carcass, expressing there not only of a precise definition, but it may be said to consist in the formation or deposition of a precise substance, which presents great variety of consistence, form, and colour; frequently assumes a definite arrangement, and possesses a peculiar organization of its own; gives rise to the gradual destruction or transformation of the tissue in which it is situated; affects successively or successively a greater or lesser number of organs; and has a remarkable reproductive tendency. Both *scirrhos* and *solidary cancer* have long been looked upon as *solidary diseases*, though not with that determination and precision of meaning which the valuable remarks of Mr. Treves are likely to establish. This cautious speaker circumscribes in a point of the order "malignant diseases," and agrees with Laennec, Carcass, and other eminent modern pathologists in estimating two species of it, the *scirrhos* and the *solidary*. It is to incalculable loss to man (not local, and consequently, the disposition to appear in one part at the same time, or to reappear when the first affected part has been freely removed, that Mr. Treves applies the term *malignant*. But it, from any local cause, a sore will not heal, or becomes gangrenous; if by the extension of the ulcerative process, bloodvessels are closed, and fatal hemorrhage ensues; if, by the production of a fistula, the patient dies exhausted; if, by the incessant irritation of the nervous system, or the morbid actions set up in vital organs under a protracted symptomatic fever, life is extinguished, the circumstances of the disease, viewed with reference to the above definition of malignancy, would not imply that its nature was malignant. (See *Med. Chir. Trans.*, vol. xv., p. 108.)

Dr. Carcass forms the essential character of heterologous formations, of which *scirrhos* and *solidary cancer* are examples, on the presence of a substance which does not enter into the healthy composition of the body, and under the generic term of *carcinoma* he comprehends *scirrhos* (*scirrhos*) and *solidary cancer* (*solidary*), with their varieties. His reasons for arranging these diseases together are the following: 1. They often present, in the early period of their formation, certain characters common to all of them, however much they may differ from each other in the subsequent periods. 2. They all terminate in the gradual destruction or transformation of the tissues which they affect. 3. They have all a tendency to affect several organs in the same individual. 4. They all possess, though in various degrees, the same reproductive character. (See *Carcass's Illustrations of the Elements of Diseases*, fasc. 2.)

But, though the varieties of *scirrhos* and *solidary*, as they are named by Dr. Carcass, resemble one another in the foregoing respects,

they present differences with this pathologist refers to two scales of the heterologous deposits, to which they owe their origin. In *scirrhus*, the deposit has little or no tendency to become organized. Its form and arrangement appear to be determined chiefly by external circumstances, and its production and increase are not directly dependent upon the nutritive function of the organ in which it is situated. In *epithelioma*, the deposit has a greater or lesser tendency to become organized; and, "although it may at first assume a determinate form and arrangement in consequence of external circumstances, it possesses in itself properties, by means of which its subsequent arrangement and development are effected, independent of the nutritive function of the organ in which it is formed, except in so far as the materials of its growth may be derived from this source." (See *Cancer*, p. 41, c.)

With respect to the varieties of *scirrhus*, when the heterologous deposit is collected in numerous points in the form of a hard, pure, serous-looking substance, intersected by a dull white or pale straw-colored trabeculae or confluent cellular tissue, it is designated *scirrhus*. When it assumes a regularly localized arrangement, so as to represent an appearance similar to a section of the pancreas, it forms what was called by Abernethy *pancreatic carcinoma*, but is better named by M. Blegny *pancreatic growth*, the term *sarcoma* being strongly objected to by some pathologists, among whom I know is Sir Astley Cooper. Again, as Dr. Carcawell observes, the heterologous deposits may be uniformly disseminated throughout the texture of an organ, which it converts into a solid substance, resembling raw or boiled pork, and named by the French *meat cancer*, or *carcinome charnu*. Lastly, when it presents the appearance of firm jelly, and is without inclosures of greater or less bulk in a multitude of cells, it is the *embryo cancer* of Leichter; the cancer *gelatiniformis* in another of M. Cruveilhier. (See *Carcawell's Illustrations of the Elements of Disease*, fig. 2.)

11. *Lacineæ* constituted the basis, which is not at present adopted, that every heterologous deposit like those of *scirrhus* and *epithelioma* cancer, having nothing analogous to them among the genuine textures of the system, necessarily and inevitably had two stages, one of *cells*, the other of *fibres*. The mistake on these points is, that the heterologous deposit does not always enter after a certain period, though it sometimes does so partially.

In the period of *crudo*, *scirrhus* is represented by Lacineæ as a substance sometimes perfectly white, but, in other instances, bluish or grayish, slightly translucent, and whose consistence is such that dividing it with a scalpel usually causes a grating sound, the consistence varying, however, in different examples, from that of the skin of pork nearly to that of cartilage. The *scirrhus scirrhus* is ordinarily homogeneous, but divided into masses, which are again subdivided into nodules, united by a dense cellular tissue, whose arrangement, though exceedingly diversified, appeared to Lacineæ to exhibit a kind of regularity, and to resemble that of the cells of a honeycomb. In some cases, the fibrous layer, intersecting the scirrhous substance, presents a reticulated arrangement; in some, an arborescent distribution; and in others, an appearance as if it radiated from a central point in every direction around. Some *scirrhus*, when laid

open, are found to look very much like the substance of a lump.

When a section is made of a *scirrhus* in its first stage, we find, according to Mr. Trauer's description, "a tough, unorganized, and purely compact mass, of a white and yellow tinge (the latter smooth, and intersected by a slightly opaque fluid); its consistence is not fusible, being hard in the centre, so as to form a nucleus. The circumference is defined by the continuation of red vessels, forming a vascular boundary" by sensation. "The texture opens up as it bends into view concentric areolæ, having three interstices filled by a white granular matter, which may be picked out from the masses. These areolæ are crossed by faint white lines at irregular intervals, in the direction of soft from a centre, visible to the naked eye, and very conspicuous under a magnifier, giving the section some analogy to that of a lemon. In the second stage, when inflammatory action commences, and is accompanied by shoots of pus, the relative firmness of the centre and circumference of the tubercle becomes reversed, the centre being paler or tougher, while the circumference retains its firmness. The surrounding pus is overladen to have lost their natural elasticity by condensation of texture, and partake of the firmness and weight of the *scirrhus*, giving considerable apparent increase of volume to the tumour, which is now well defined at its margin, and is lost of a compound character." One particular opinion entertained by Mr. Trauer is, that the dense organs white lines, which, traversing the tumour in the direction of radii, and which is denser as they proceed outward, are not the trabeculae of the fibrous, but the septa, which divide and support the lobules of which the gland is composed, in an opaque and thickened state. (See *Med. Clin. Trans.*, vol. vi., p. 186.) The correctness of this view seems possibly doubted by the fact that the radiating white lines are met with wherever the scirrhous lesion is met with, whether in a gland or not, and sometimes shoot into the surrounding texture beyond the limits of the part originally attacked.

Notwithstanding the essential difference between *scirrhus* and *epithelioma*, seems to Dr. Carcawell to consist in the former having little or no tendency, the latter a greater to become organized, to become organized, it is sometimes impossible to draw a distinct line of separation between them; for the heterologous deposit, when first formed, and, indeed, frequently for a considerable time after its formation, does not furnish any signs which show that it will or will not become organized. 1. The heterologous substance may exist in the form of *scirrhus*, *pancreatic carcinoma*, or the *indurated tissue*, without presenting any trace of organization; the texture which it involves being gradually destroyed by its presence, and both ultimately converted into a soft, granular, pulpy, or *liquid* mass, of the colour or consistence of *crudo* or *meat*. 2. The heterologous deposit may exist under the same forms, but change into *imaginary* or *transitory* *scirrhus*, becoming more or less soft and vascular, and frequently terminating in *abscesses* by the rupture of its vessels, or in the state *hemorrhagic*, but improperly termed *fungus hemorrhoides*. According to Dr. Carcawell, numerous examples might be given of *scirrhus*, *epithelioma*, *sarcoma*, and *fungus hemorrhoides*, arising in the same initial state, and passing alternately from the one into the other in the order here

gated. Indeed, all the varieties, both of sarcoma and epithelioma, are frequently met with, not only in different organs of the same individual, but even in a single organ. (See *Crawell's Histogenesis of the Epithelioma of the Bladder*, p. 2.) A tumor which I lately removed in the North London Hospital exhibited, in some places, fine specimens of mammary sarcoma, while in others its consistence was cartilaginous or medullary. Sir Ashley Cooper once mentioned to me a case in which he removed a diseased breast, the substance of which corresponded to sarcoma; a return of disease took place, and the tumor was then of the medullary kind. A mucous texture of an unaltered form is rare in young persons. The examples in which it presents itself, in combination with medullary cancer, are principally noticed in individuals who have passed the middle period of life. Several of the varieties of both species of carcinoma appear to Dr. Crawwell to differ materially from one another with regard to the comparative rapidity of their development, as well as their reproductive tendency; a fact of considerable practical importance. In both these respects, the papillary differs from the lobular, the medullary from the fungiform, and the mammary from the medullary cancer: the first often remaining stationary for months or years; the last frequently acquiring its maximum of bulk in a few weeks; and, when removed, being sometimes reproduced with a degree of tendency which is never observed in any of the other varieties. Generally, the more the varieties of sarcoma and medullary cancer partake of the characters of cellular, cellular-fibrous, and fibrous tissues, soons, granular, the less rapid are they in their growth, and the less is their tendency to be reproduced. (See *Crawwell's Histogenesis*, &c., p. 2.)

If the disease be examined at the earliest period of its formation, while the heterologous substance has not effected the particular texture of the part in which it is contained, the resemblance of Dr. Crawwell proves that the *urinary substance* becomes manifest to our senses, either as a production of nutrition or of secretion. "In the former case (says he), it is deposited in the same manner as the nutritive element of the blood, enters into the molecular structure, and assumes the form and arrangement of the tissue or organ into which it is thus introduced. In the latter, it makes its appearance on a free surface, after the manner of natural secretions, as on various surfaces in general."

Another interesting fact in relation to cancer is, that the heterologous substance is sometimes found within the vessels. According to M. Andral, solid fibrine in the blood-vessels sometimes constitutes in organs whitish masses, similar to cancerous tumors. In the body of a milled-up man he found one of the lungs full of masses of this description. The middle ramifications of the pulmonary artery were packed with solid matter, of a dirty-white color, reddish at some points, and at others liquid, and like grayish bouillie. On being attentively examined, it seemed to M. Andral to be nothing more than solid blood, related to elementary fibrine, with a little of the coloring matter at some points, and here and there in a state of coagulum. M. Andral traced a similar matter to the smallest vessels, as far as he was able to follow them, and he was convinced that the whitish masses with which the lung was studded, instead of being a degeneration of the organ or an accidental production, as

it really consisted of small vessels filled with solid fibrine, more or less destitute of coloring matter. M. Andral likewise ascertained that cancerous masses are sometimes met with in the ramifications of the vena porta. He noticed the same thing in the kidney: a fibrous coagulum, of a dirty white color, was found occupying the total vein, to the extent of which it was adherent; and it extended into the ramifications of the vessel, so that it could be traced into the smallest branches, and into parts of the kidney where, previously to the dissection, only white or pale red masses had been seen, which Laennec would have termed the trophoblastic (medullary) matter in a state of coagulum. M. Velpeau, who had observed similar facts, was led to infer that cancer may be primarily developed in the blood. But, instead of adopting this conclusion, M. Huguier, under the name introduced by M. Andral, in which a certain change of the form of the blood is supposed to have an important share in the formation of some cancerous productions, (See *Dict. de Méd. et de Chir. Prat.*, t. ii., p. 12.) As Professor Cuvier remarks, the presence of the heterologous substance, which constitutes the several varieties of both species of carcinoma in the blood, is a circumstance of great importance; and, unless it be clearly demonstrated to arise in consequence of a modification of the blood itself, we should find it impossible to explain many of the phenomena which it presents, more especially those which accompany its formation in the molecular structure of organs and on the free surface of membranes. The following facts are regarded by Dr. Crawwell as furnishing strong evidence that the formation of this substance takes place in the blood, whether it be found in this fluid alone, or in other parts of the body at the same time: The presence of this substance, 1. In the vessels which supply in carcinomatous tumors, or in their immediate vicinity. 2. In the vessels of a portion or of the whole of an organ, in the former of which this substance is exclusively confined, and can be traced from the trunk into the branches and capillaries. 3. In vessels having no direct communication with an organ affected with the same disease; as, for example, when it is confined to a small extent of the vena porta; and, lastly, in blood which has been affused into the cellular tissue, and on the surface of organs.

Dr. Crawwell further observes, that the divisions of the vascular system, in which the cancerous substance has been observed, are the venous and capillary; and that in large veins, such as the vena porta and its branches, the malignant vein, &c., it may present the lobular, medullary, medullary, or branched characters, all at the same venous trunk.

The formation of these varieties of carcinoma in the blood is a curious and particularly interesting fact, more especially as bearing upon the long-disputed question whether cancer is a local or a constitutional disease. Dr. Crawwell believes that when the disease takes place in the intimate structure, or on the free surface of organs, its natural element is separated from the blood, and deposited under a variety of circumstances which modify its form, bulk, color, and consistence. He cannot, therefore, unite some pathologists, who regard the seat of the two principal varieties of carcinoma as limited to any one tissue, or who refer its origin to any modification of structure or special organization; and, with respect to the cystic origin of cancer,

point, as suggested by Dr. Hodgkin (*see Med. Chir. Trans.*, vol. xv., p. 202), he remarks, that the presence of cysts in the liver, walls of the stomach, lungs, kidneys, brain, lymphatic glands, spleen, and blood, is not to be detected at any period of the development of carcinoma, and, therefore, when they do occur in adult organs, as the ovaries, testes, mammae, &c., they must be regarded as a mere coincidence, or as a consequence of the disease, and not as a cause or necessary condition of it. (*See Carc. Illustrations of the Ethn. Form. of Dupuy, loc. 2*) The latter conclusion, I believe, has long been the prevailing one. We find it adopted by Home, Abernethy, and Travers. The latter remarks:—"Within the wall of the bladder, one or more cysts, containing a dark yellow or coffee-brown fluid, are sometimes met with, but are often not present." (*See Med. Chir. Trans.*, vol. xv., p. 202.)

Cuvillier regards all organic transformations and degenerations as exclusively the result of the deposition of morbid products in these living elements of organs, and he believes that these *three* phases are incapable of undergoing any organic lesion except hypertrophy and atrophy. But this view has been proved by Dr. Carc. to be incorrect, who shows that in the liver and stomach carcinomas can be distinctly seen to form in the histologic structure of proper tissue.

The form assumed by the carcinomatous matter seems to Dr. Carc. to be determined, in a great measure, by external circumstances. The globular shape usually occurs in organs possessing uniform density, and in parts situated on all sides to equal pressure. On natural and accidental serous surfaces, although the deposits may be at first globular, & frequently become pyramidal, either on account of the mode of attachment, or of less resistance being made to its growth in one direction than another. It assumes a fungiform shape when placed in circumstances facilitating its lateral or extending its anterior development, as when it meets with a dense, unyielding substance during its progress, or, having pierced the skin, is subjected to pressure. When accumulated in separate portions of the cellular tissue into rounded masses, grouped together, and included within a connective capsule, it generally presents a lobulated appearance, and, in the subcutaneous tissue in particular, it frequently exhibits the cauliflower or mulberry appearance. (*See Carc. Illustrations, &c.*)

This current pathological text notices the cauliflower arrangement of carcinomatous matter, as principally met with in the subcutaneous cellular tissue, and frequently in the form of thin vesicular patches, varying from the breadth of a pin's head to an inch or more. The cauliflower arrangement and modifications of it seem to him to depend upon the carcinomatous matter being retained in the veins, lymphatics, or lactals.

With respect to size, Dr. Carc. explains that the quantity of carcinomatous matter deposited in the molecular structure, or on the free surface of organs, is extremely various, but perhaps never so great in the former as in the latter. In the liver it may vary from the size of a pin's head to that of an orange. In more yielding organs, as the lungs, testes, and even the mammae, it may equal in bulk the head of an infant or of an adult, as exemplified in a case presented at University College, London; and, in the intermuscular and subcutaneous cellular tissue, the bulk is sometimes still more considerably,

Dr. Carc. very properly draws the attention of his reader to the influence of pressure in promoting or retarding the development of carcinomatous tumors. While their progress onward is resisted by an unyielding fibrous structure, they often remain for a considerable time nearly stationary; but, directly this obstacle is removed, they acquire a rapid increase of bulk, and, as soon as the skin sloughs, they often protrude the shape of enormous fungus.

The carcinomatous swellings which strike a very considerable size are not those of a sarcoma, but of a medullary texture. In fact, as Dr. Carc. observes, the tumor grows within themselves the power of increasing to an almost unlimited extent. It is to the cellular organization of such tumors that the rigidity of the growth, and their frequently great bulk, are to be attributed. A boy came to the North London Hospital with a medullary tumor, about the size of an orange, situated over the lower edge of the scapula; on ten days it occupied the whole of the axilla, reaching partly over its anterior margin, as well as very deeply into it.

I have already alluded to Laennec's doctrine that the consistence of cancer varies, and that it is greater in the early than the late stage. The term *scirrhus*, implying induration, is commonly employed to express the early, or solid stage of cancer, while a softer condition of the part or tumor is frequently confined to indicate a more advanced period of the disease. But, as Dr. Carc. remarks, the degree of consistence of carcinomatous formations is not an applicable character of a particular stage of the disease itself; for, when first perceptible they may be as hard as cartilage, soft as brain, or fluid as cream; or they may become soft or fluid, after having remained for a certain time in a state of hardness.

The variety in the consistence of carcinomatous formations is accounted for by Dr. Carc. to the following circumstances: 1. The nature of the organ in which the carcinomatous deposits are contained. 2. The chemical composition of the deposits. 3. The subsequent changes, occurring either in the deposits itself, or in the tissue with which it is in contact.

According to the analysis of scirrhus and medullary deposits, published by Lousin (*Trat. de Anat. Pathol.*), seventy-two grains of scirrhus least contained:

Albumen	2 grs.
Gelatin	10
Fibres	20
First fatty matter	20
Water	20
	70
Seventy grains of scirrhus thus combined.	
Gelatin	15 grs.
Fibres	10
Fatty matter	10
Water	25
	70

In the early stage of medullary cancer, the tumor contained a greater quantity of gelatin than scirrhus; and in the more advanced stage, when the carcinomatous matter varied in consistence of soft brain, the albumen was much more abundant than the gelatin. The same must be worthy of attention, now that medullary tumors are frequently termed *adenomas*.

According to the important researches of Prou-

Some Carcinoma, when we examine anatomically a mass of carcinomatous matter contained in a large vessel, or situated on the surface of a serous membrane, in loose cellular tissue, or on the surface of a bone or cartilage, we find it composed of the following elements in various proportions, viz., carcinomatous matter, cellular, fibrous, and serous tissues, and bloodvessels. The carcinomatous matter almost always forms by far the greater bulk of the disease. If its consistency be considerable, it presents a uniform granular or nodular arrangement; if soft, a lobulated one. The cellular tissue is found in small quantity, and so fine as not to be perceptible till the carcinomatous matter has been separated from it by pressure or incision. The carcinomatous matter is enclosed in it, and separated by it into granules, lobules, &c. These it intersects in various directions, and it serves to conduct the vessels which contribute to the nutrition and growth of the disease. The fibrous tissue is less frequently an element of carcinoma than the surfaces of organs; but the serous is often present, either covering the carcinomatous matter encysted, or forming cysts in it of various sizes, filled with gelatinous, albuminous, or other fluid. When carcinomatous matter is deposited in the medullary structure of organs, the quantity of cellular and fibrous tissues intersecting it in various directions is sometimes very considerable. (See *Carroll's Illustrations of the Elementary Forms of Disease*, p. 3.)

In true scirrhus the traces of vascularity are very faint, but in medullary cancer the abundant bloodvessels demonstrate a high degree of vascularity. The vessels resembling in them are not only numerous, but large. By some they have been considered principally arterial; by others, venous. Dr. Hodgkin is not able to decide to which class of vessels they are most nearly allied. These newly-formed vessels, though large and numerous, are extremely weak and fragile, and derive little or no support from the structure by which they are surrounded. Hence they are liable to give way at numerous points, whence proceed those frequent and extensive hemorrhages which have led to the disease being sometimes named fungus hæmatodes. (See *Hodgkin, in Med. Chir. Trans.*, vol. xv, p. 324.) According to Dr. Carwell, the vessels of epithelioma, or medullary cancer, vary in diameter from the breadth of a hair to that of a line, and grow in that peculiarity of distribution always more or less congested in newly-formed vessels, namely, the ramifications of which they are composed communicate with a common trunk at its opposite extremities, in the same manner as the hepatic and splenic divisions of the vena porta do with the trunk of that vessel. They are frequently ramous, and even to Dr. Carwell to partake more of the vessels than the arterioles character. He describes them as formed apart from the vascular system of the surrounding tissues, and constituting Geryper's circles of epithelioma. "The communication which exists between these vessels and those of the organ in which the carcinomatous substance is contained is frequently very imperfect, a circumstance which, together with the delicacy of their structure, renders them extremely liable to congestion and rupture. The most minute divisions of these vessels terminate by crystallized extremities in the carcinomatous matter, where they communicate with veins and arteries belonging to the affected organ. The latter vessels, which may

be said to form the callosities or capsules of epithelioma, are seldom so conspicuous as the former; but there are cases in which they appear to constitute the greater part of the vascular structure of the disease." The arteries and veins of scirrhus or scirrhus are only those of the vessels of neighboring tissues, which have become enclosed within the histological substance. (See *Carwell's Illustrations of the Elementary Forms of Disease*, p. 3.)

Nerves have never been detected in any of the varieties of carcinoma as a new formation; but they are sometimes included within agglomerated ligaments, or even in a single tumour that has happened to form in a situation through which they pass. (R.) Dr. Hodgkin is not aware that even a single nervous fibre has ever been discovered in the essential part of the adenoma growth. (See *Med. Chir. Trans.*, vol. xv, p. 226.) But, though the substance of medullary cancer is not supplied with nerves, the nerves may become the seat of the disease. This has often taken place in the optic nerve. (See *Wardrop on Pseudo-Hæmatodes*.) M. Jules Cloquet records an instance in which a carcinomatous tumour was situated in the great sciatic nerve, immediately below the quadratus muscle. At some points it was very firm, at others soft, while in particular parts of it there was an obscure feel of fluctuation. Its colour was a lustrous red, and its surface streaked with vessel capillary vessels. Some of the posterior filaments of the sciatic nerve passed behind the tumour, and were separated from one another on a level with it, but without any perceptible change in their organization; all the others were lost in, and complicated with the adenomatous growth, which consisted of the scirrhus and carcinomatous matter blended together, and presenting a marked appearance. (See *Jules Cloquet, Pathologie Chir.*, p. 187, fig. Paris, 1831.)

Mr. Cesar Hawkins concurs with the observations made by Sir Astley Cooper, M. Andral, and Professor Carwell, that cancer and encysted ligaments are allied to one another, so that the two structures may be found together, or a tumour of one kind removed from a part, may be followed in the same place by another of the opposite kind. "Even the local character of the scirrhus may be succeeded by fungus hæmatodes; for a case of chimney-sweep's cancer has been published by Mr. Langstaff, which was operated upon, and the patient died of fungus hæmatodes of the os innominatum, venter glands, and liver." (See *Lond. Med. Gaz.*, August, 1834, p. 681.) I have heard of several other cases confirming the truth of this observation; and one I saw myself, in a patient of the Brompton Dispensary.

Mr. Hawkins justly observes that some parts are more liable to one form of cancer than another. Thus scirrhus is common in the breast, but fungus hæmatodes (medullary cancer) rare; while the latter disease is frequent in the testicle, and the scirrhus variety of cancer rarely seen in it. Fungus hæmatodes of a single, or other well-textured, rare a different course from the same disease in a bone; and cancer is modified, according as it occurs in the breast, stomach, or uterus. In the skin, particularly, a considerable difference is observed in its appearance, progress, and degree of malignancy, from cancer at other parts; and even different parts of the skin are, in some respects, differently affected. (See *Haskin, Op. et. vol. vii., p. 685*.)

EXTERNAL CHARACTERS OF SCIRRHUS.

It was a remark made by Sir Richard Bright, that when this disease originates by a small portion of the glandular structure of the breast becoming hard, it may be easily distinguished by the hard part never having been previously circumscribed, and giving more the feel of a knot in the gland than that of a swelling distinct from it. The disease begins at a small spot, and extends from it in all directions like rays from a centre. This is one feature distinguishing this disease from many others, which at their first attack involve a considerable portion, if not the whole of the part in which they occur. Aberrantly conceived that, though a true scirrhous might be shrank, it could not be made to recede by the treatment which lessens other swellings. On this point, however, he was not positive; for other surgeons had informed him that diseases which eventually proved to be cancerous had been considerably lessened by local treatment. It is to be recollected, however, that some tumours which end in cancer are not born the first of this nature; consequently, in their earlier stages, they may yield, in a certain degree, to local applications, but completely resist these when the cancerous deposit has begun. Still we have the authority of Young, Remazez, Carcass, and others, for the fact that the growth of cancer may be retarded by methodical pressure, and sometimes the disease even cured. Perhaps, therefore, to assert that a scirrhous swelling is absolutely incapable of any diminution, would not be correct. We lately had a woman in the North London Hospital whose breast I removed on account of a true scirrhous. The disease, unfortunately returned in the form of hard tubercles in the skin, as well as an extension of the glands of the axilla and above the clavicle. Now, in this instance, the hard masses in the skin were observed to be much smaller at some periods than others. A scirrhous tumour is sometimes surrounded by more or less inflammation of the adjacent textures; and, upon the subsidence of it, the swelling will, of course, appear lessened. Notwithstanding these circumstances, the hardness of a scirrhous swelling to be diagnosed or diminished may be set down, without risk of inaccuracy, as one of its most confirmed features.

Another character of scirrhous is to involve the contiguous textures in the same diseased action. The skin, the cellular tissue, the muscles, the pectoral, &c., all become implicated, sooner or later, if they are in the vicinity of scirrhous cancer. In this respect Abernethy recognised no difference of it from testicular cancer, which is propagated along the ductum system, while the parts immediately in contact with the enlarged glands do not generally assume the same diseased action.

As a scirrhous tumour increases, it generally, though not constantly, becomes unequal upon its surface, so that this inequality has been considered characteristic of the disease. The circumstances influencing the shape of the carcinomatous deposit, according to Professor Carcass's views, I have already explained; they prove that the mere shape of the swelling is not a criterion of its nature.

Abernethy pointed out the error of dwelling too much on locomotion pain as a test of a scirrhous tumour: first, because it does not prevail in every case, or in every stage of disease in which it does occur; and, secondly, because it is a

symptom attending other tumours which are scirrhous in structure. (See Abernethy's *Essays*, vol. II, p. 16, &c.) M. Bérard agrees with Abernethy, that locomotion pain is by no means a characteristic sign of cancer; and it seems to him only to take place under circumstances where the disease is situated in an organ which is penetrated or surrounded by a greater or less number of nerves derived from the medulla spinalis, and suffering irritation. This happens especially in cancer of the breast, testis, and neck of the womb. As for cancer (scirrhous?) of the liver, kidneys, spleen, and lungs, it is alleged by M. Bérard scarcely ever to produce any locomotion pain, except when the disease has extended beyond the peritoneal cavity. (See *Dict. de Méd. et de Chir. Français*, t. II, p. 431.) The best of scirrhous tumours being often unaccompanied by such pain is now so generally known, that I shall merely add the evidence of Mr. Traube on this interesting point. "Not unduly," (says he) "the scirrhous tumour is perfectly silent, from the period of its formation to the close of life, undergoing very slight, if any increase, and giving, when much enlargement is approached, no trouble to the subject of it. A lady now under my observation has been many years so situated, enjoying uninterrupted health, though considerably above 70 years of age. The tumour is of the size of a hen's egg, and has the genuine scirrhous character. She takes nourishment as a beverage; and the probability is that when in no degree affects her health will not eventually shorten her life. (See *Med. Chir. Trans.*, vol. xv, p. 214.)

Scirrhous tumours are mostly developed slowly, without any perceptible increase in the temperature of the part, unless the texture, among which the cancerous deposits him, happens to be the seat of inflammation. As for the heterologous substance most, M. Bérard correctly regards it as a kind of foreign body, which may mechanically irritate the organs and textures in which it is placed, or more or less seriously impede their functions, so that when some are of first rate importance in the economy, the result is inevitably fatal.

A scirrhous swelling rarely, or I may say, never assumes the magnitude which the possibility of other swellings are disposed to affect. According to Sir Astley Cooper, it usually increases from the size of a marble until it requires two or three inches in diameter. "So," he truly observes, "that the true scirrhous tumour increases to a very considerable bulk, and this circumstance is one of its criteria." (See *Lectures*, &c., vol. II, p. 177.) Many scirrhous are even attended with a diminution or atrophy of the part. The presence of the heterologous elements in the surrounding textures fully explains these occasional partial and total atrophies.

By some writers, imbricated with the pathological anatomy of scirrhous, it has been asserted that tumour is not an essential character of the disease. Now this observation is only correct in a certain sense. "It is true," (says Sir Charles Bell) "that there is not always an increase of the dimensions of the whole breast; on the contrary, true carcinoma is often accompanied with contraction and diminution of the general bulk. But what is true of the breast or mamma is not true of the tumour; for the proper structure of the gland either atrophies or is progressed; and sometimes the surrounding fat is diminished by absorption, so that the whole mass is less than the

natural breast, or than what the breast was before the commencement of the disease. But still the diseased part is properly a tumour; there is an increased mass, a protrusional growth, or new matter, corresponding to the old definition without exception. But farther, and in respect to the surface membrane, the fat is not always diminished in carcinous mamma; but sometimes quite the contrary; and this difference is it will sometimes produce a variety in the external character, when there is none in the disease actually, or in the internal structure. Sometimes, from the disposition of fat, the irregular tuberculated structure of this disease will be apparent to the eye and to the touch, while in another patient the breast will be large, full, and smooth, only marked more than naturally with large blue veins, and having an ulcer like a hole in the centre of the breast." (See *Med. Chir. Trans.*, vol. xlii, p. 220.)

A truly carcinous tumour of the breast; capable of changing into open cancerous ulceration, and of a certain size, as described by Sir Edward Jenner as hard, heavy, and closely connected with the mammary gland, and, when moved the whole gland moves along with it. When, indeed, all the following characters are possessed, no doubt can exist about the nature of the disease: an early puckering of the integuments; a dull brown, or leaden-coloured appearance of them; a knotted, uneven feel to the swelling; occasional darting pain in it; an early fixed attachment of it to the skin above, and percolate outside underneath; and a retraction of the nipple. According to Sir Charles Bell, it is the ligamentous bands which produce the retraction of the nipple, by extending between the ducts, and destroying its spongy texture. (See *Med. Chir. Trans.*, vol. vi, p. 224.)

Mr. Trauer's description of the external characters of scirrhus is one of the best which I am acquainted with. "Hardness (says he), with increase of weight, indurability or toughness in some cases, knotty or craggy induration in others. Circumscription and mobility beneath the skin in its earliest stage, but not to such a degree in the subsequent feel as to allow of the fingers passing between the tumour and turning its edge upward. Next, &c., in the second stage, close adhesion to the tegument, and such incorporation with the glandular organ in which it is seated as to have its mobility lost; that of the gland itself upon the parts beneath. The adhesion of the skin either stretches, or partially betrays and puckers it, according to the smooth or irregular surface of the tumour, or to the close or loose attachment and particular conformation of the integuments at the seat, as, for example, next the nipple, and at a distance from it, or beneath the areolar membrane of the pyramis or areola, and the contiguous integument of the body. Third stage; contraction and distortion by pressure of volume in the gland as the tumour increases. Almost protrusion of one large, coloured tubercle, sometimes of several smaller tubercles or nodules. Irregularities of volume and hardness by topes or nodules. Transient pains, which have been likewise obscure and occasional, now more distinct and frequent, like the pricking of a sharp instrument, with a sense of heat or burning. Dusky or livid red colour of the skin, with repulsive tension. Extension or cracking of the skin at the summit or base of the tubercle, and fragrant eruptions, with ichthous and sanious odour. None of these signs is indispensably

diagnostic." (See *Med. Chir. Trans.*, vol. xv, p. 225.) To continue the same gentleman's description, the ulcerative process at length opens the tumour, when the cracked and livid integument, previously exuding a sanious white, viscidulent fluid, and the external opening is sometimes enlarged by a partial sloughing of the integument. Suppuration now takes place in the surrounding cellular membrane, and, as granulations spring up luxuriantly from the sides, the centre of the tumour caves, and becomes a cavity more or less considerable. The granulations have a spongy or fungoid character, and are elevated and broadly crested as to give the appearance of additional depth and breadth to the sore. "As the sloughing process enlarges and deepens the centre, the disease becomes exceedingly offensive; and although granulations continue spreading circumferentially as the ulceration, they have not the power of maintaining their vitality. This means that we attempt to preserve the ulcer from foulness and fever by different applications; we can render it clean, but in a day or two the newly-formed surface almost always retreats towards the centre." (See *Med. Chir. Trans.*, vol. xv, p. 211.) He adds, that in scirrhus it is not suppuration which, as in scrophulous and other tumours, brings the disease to the surface, nor does the skin ulcerate until after the wound. "Decomposed by a dense wall, the centre breaks up by necrosis, constituting the state of indurated cancer. Indeed, the scirrhus is seldom removed so early as to be found with its nucleus unbroken." (P. 213.) This observation agrees with that of Laennec respecting the softening process, who only erred in representing it as invariably taking place.

On dissection, Sir Astley Cooper observes that the breast is one solid mass, like cartilage, with very little vascularity except at its edges, and internally fibrous. When the breast has acquired any magnitude, he says there is generally an opening in it, in which case it has the appearance internally of being water-soaked and spongy. In the situation of the ulceration it is very vascular, and bloody serum is met with. The adjacent glands put on the same character as the scirrhus breast. The cellular membrane, skin, and arteries are also affected. Sometimes the diseased glands above the clavicle press upon the thoracic duct, and thus interrupt the transmission of chyle into the blood. Hence the appetite is sometimes voracious, though the patient is rapidly wasting. In the chest, on the same side as the disease, hydrothorax prevails, and the discontents of the pleura are in a morbid state, and small white spots, like pine heads, are visible. Trench of scirrhus disposes Sir Astley Cooper likewise represents as occasionally existing in the liver, uterus, &c.

But, on the other hand, attempts have been made by Hunt, Brouncker, and Alibert to represent the disease by inoculation, but always without any result in proof of the existence of a virus. The fact of the substance of cancer being often found within the bloodvessels, the same heterologous matter as is deposited out of them, sufficiently proves to my mind that the disease is constitutional, and depends upon a poison by which the adventitious substance is formed in or from the blood itself.

I once attended a woman who died of cancer of the uterus, and in the same room was her mother, all the forepart of whose chest was in a

ment, mutilated state from the effects of sloughing, by which, at different periods, she had been freed from tumors of both her breasts. Baron Dupuytren believed that it was particularly when the cancerous mass was encysted that the whole of it was capable of being destroyed by caustic, and the patient completely cured. (See *Journ. Hebdomadaire de M.-L.*, t. iv., p. 38.) Many years ago, Mr. Clark had a patient in St. Thomas's Hospital, in whom the sloughing process went on to such an extent, under a largest scutcheon, that the nose afterward healed soundly. "I have seen (says Mr. Travers) more than one case in which extensive gangrenes of noses existed, with much puckering and stretching of the skin of the chest, and no vestige of the breast remaining. In one of these, the patient, a lady in Berkshire, resisted the pressing advice of a consultation of London surgeons to allow the extirpation of the tumor, twenty years since. She has been in the constant habit of taking the medicine here prescribed, the extract of henbane, almost at bedtime. She is still alive, healthy-looking person, as formerly, and attributes her cure to the medicine." (See *Med. Clin. Trans.*, vol. xv., p. 218.)

Metastatic compression was first recommended and justified in this country, as a means of curing cancer, by Young; and the same practice was afterward put to the test of experience in the Middlesex Hospital, from which institution the report of Sir Charles Bell tends to prove that compression, applied either to scirrhous or to ulcerated cancer, is decidedly harmful. M. Roussel and Ferrus also came to the same conclusion. (See *Dict. de Mef.*, 1822.) The principal advocate for it at present is M. Recamier, who attributes the failure of it in the Middlesex Hospital to its not having been applied in a suitable manner, not modified according to the stages of the disease. M. Recamier combines likewise the administration of henbane with a very low diet, and he observes, that the latter medicine produces scarcely any effect. (See *Recherches sur le Traitement du Cancer par la Compression*, Single et Goubaux, 8vo, 2 tomes, Paris, 1829.) I lately tried Recamier's plan in a case of scirrhous in the North London Hospital, but it seemed only to accelerate the conversion of the disease into open cancer.

An escharotic, which has been of late strongly recommended for cancerous affections, is the chloride of zinc, employed in the form of paste. On this subject my friend, Mr. Gross, of Norwich, observes, "It can, of course, only avail where the disease is still local; but the cases related by Drs. Compton, Ure, and Rodger, many of which occurred under the eye of most able surgeons, prove that this escharotic destroys the scirrhous tumour speedily, leaving an ulcerated surface, which often readily heals; and, moreover, it induces no danger from absorption, which is a recommendation not possessed by the actualized paste." The crusts being first removed by a blister, the plastrum of paste is applied, composed of one part of chloride of zinc and two of sulphate of lime. (See *Lippincott's Med. Gaz.*, vol. xxi., p. 287; *Compton, Mémoires sur un Nouveau Mode de Traitement des Affections Cancerieuses*, Paris, 1836; and *Requien, New Treatise of Malignant Diseases and Cancer*, Lond., 1834.) This writer states that the paste not only destroys the tumour, but purifies the surrounding atmosphere. He uses the chloride of zinc, mixed with different proportions of flour, and has applied it to a chancre on the inside of the mouth, and also to

the os ment, with a good result. (See also *J. G. Compton in Proc. Med. Trans.*, vol. v., p. 23.)

Dr. Ure, in some observations on hypos, recently published, comminates the following particulars respecting the chloride of zinc. "The preparation of the chloride, which I presented and introduced into practice in this country, differs in a most important feature from that originally employed by M. Compton. The wheaten flax prescribed in the French formula is a spiritless vessel the chloride in a glassine dish, which plants its power, or, at any time, tends to confine its action to the particles on the surface of the paste; but the amorphous crystals of my formula, while it can exercise no chemical action upon the chloride, forms a porous medium, through which the whole of the particles of the subsequent chloride may transude upon the naked and tumorous tissue, with the effect of dissolving or dissolving it with certainty, to any desired depth. This preparation of mine has been adopted in several of the London Hospitals, and has been found to be uniformly in its action successful." (See *Land. Med. Gaz.*, Dec. 2, 1835.) The action of the chloride, and also of the chloride of zinc, upon albumen, and their consequences in relation to the albumen of cancer, are described in a paper by Dr. J. C. Warren.

[Dr. J. C. Warren has removed three hundred cancerous breasts, one sixth of which have been permanently successful, no more of the disease having occurred as far as is ascertained, which, if truly intermediate, is unprecedented.]

Dr. Joseph Parry, of Philadelphia, has left a valuable paper on the affections of the mamma liable to be mistaken for cancer. (See *N. A. Med. and Surg. Journal*, vol. v., p. 239; and in the sixth volume of the same journal, p. 334, will be found another paper by Dr. P. on the diagnosis and treatment of cancer.)

The experience of Professors Gibson, Yell, McClellan, Ure, and, indeed, that of nearly all from whom I have heard since America was known, in operations for the removal of cancerous mammae, is, that, when the disease has been preceded by scirrhus, and especially if the axillary glands have suffered, the curement is restricted in scope of the glandular tissue, and ultimately fatal. When, however, it has not been preceded by scirrhus, the cure by extirpation is often found to be permanent. Dr. Ure, of Glasgow, has lately removed a cancerous lip by the method of Velpeau, extending the incision upon the interior of the lip, and relying upon effecting subsequent union between the skin and mucous membranes by the oxyphosphoric solution. The operation was completely successful, though the patient was of very advanced age.—BATES.]

[CANGRUM ORIS. It is a perfect species of phagedenic ulceration, and in its worst form not unlike hospital gangrene, as I have seen several deplorable instances of. It also resembles the ulceration and sloughing in the mouth produced by mercury. The cancerous inflammation of the preputia of children is of a similar character. (See *Kidder's Med. Clin. Trans.*, vol. vi.)]

The disease is rarely seen, is slow, but not constantly in children from the age of eighteen months to that of six or seven years. The gums, as well as the lips and cheeks, are sometimes affected, in which circumstance the mouth is generally excruciating and loath. The ulceration is

usually attended with sloughs, which burst either through the cheek, lip, or just below the jaw. Eruptions are not frequent, and, when the disease is neglected, extensive sloughing sometimes happens.

According to Dr. Cuning, in most instances the ulceration, commencing in the gums, extends to the lips and cheeks, but sometimes it begins in the innermost transverse of the lip or cheek, and thence extends to the gums. This disease is set down by Dr. Cuning as most frequently making its attack during the period of the first dentition, though often met with in children between three and seven years of age.

When the disease occurs in infants on the breast, it is generally attended with a purplish and spongy appearance of the gums and roof of the mouth; and the ulceration, which lays bare the necks of the teeth, both externally and internally, is of a greenish or ash-colour, and very much discoloured blood. The salivary discharge is increased; the tongue is white; the mouth feels hot; the bowels are for the most part confined; and the child in general, exhibits under a greater or less degree of fever." (*See Dublin Hospital Reports*, vol. ix., p. 381.) Dr. Cuning has not seen this form of the disease personally, to the irritation of the four upper incisors, but he has frequently seen it when the child had only six or eight teeth; and he has constantly observed that, when it occurs thus early, it is the upper gum that is first and principally attacked. This appears to Dr. Cuning the mildest and most curable form of the disease, and he describes it as rarely attended with sloughing.

The second variety noticed by Dr. Cuning occurs in children between the ages of twenty months and seven years. The ulceration especially begins in the gums, whence it extends to the lips or cheeks. Sometimes it is of an acute, sometimes of a chronic nature, and attended, accordingly, with more or less sloughing. In the very worst forms, however, though the sloughing is considerable, the ulceration is always predominant. (*Op. cit. vol. cit.* p. 341.)

The third variety described by Dr. Cuning is at first confined principally to the cheek or lip. It begins with ulceration of their membrane, which is soon followed by that hard, red, shining, and circumscribed swelling, which, if the disease be not arrested, will speedily pass into gangrene. In this variety gangrene predominates over ulceration, and the constitutional disturbance resulting from it may prove fatal.

Living in a marshy situation, want of wholesome food, and attention to cleanliness, are conducive to this disorder, which is often met with in houses where children are crowded together. One of the worst cases, however, which I have ever seen, was in a child of an opulent family in Essex. The complaint is sometimes suspected to be contagious.

The first or mildest form is well known generally to admit of being cured by purgatives, aided by some of the applications presently specified.

In the second form, Dr. Cuning, after cleansing out the bowels with a weak cathartic, confides chiefly in an alterative of mild purgatives with astringents. The local applications preferred by him are the black wash, and a dilute solution of mercuric acid in honey. When the ulcerated surface is in contact with canines or loose teeth, these should be removed. Dr. Cuning tried the

liquor arsenicalis and cold salt-water-bath with-out advantage.

In the third variety, where gangrene is predominant, the disease rapidly proves fatal. Dr. Cuning has employed various local applications, such as the mineral acids, dilute and pure; the oxygal argentea, the butter of arsenic, solution of the nitrate of silver, the black wash, &c., but mostly without any good effect. I have likewise tried all these applications in vain, as well as solutions of the chloride of soda of different strength. With such external means, cinchona, sulphate of quinine, carbonate of ammonia, opium, and wine, have been prescribed, all for the most part, unavailingly. (*See Cuning in Dublin Hospital Reports*, vol. ix., p. 383, 385.)

The treatment recommended by Dupuy consisted in administering mercuric acid internally, using it as an application to the disease; giving the patient a nourishing diet, with jelly, wine, &c., and occasionally presenting an emetic.

In the worst form of the disease I have found the concentrated nitric acid one of the most useful applications, especially when noticed with the internal exhibition of sulphate of quinine and diasterephoric acid.—C.]

CARBUNCLE. Besides the diffuse forms of abscess and phlegmon of the subcutaneous cellular tissue, there is likewise "a circumscribed form," which is observed in furunculosis, carbuncle, or boil. The great accumulation of blood, and the still greater and rapid effusion of pus, which takes place in these circumscribed acute inflammatory affections, produce a state of extensive induration of the cellular tissue, a greater or lesser portion of which, long time as it is stagnated, dies from want of nutrition, becomes separated from the living parts, and is expelled in the form of a gray or straw-coloured spongy or jellyy mass, through an opening made in the skin by a similar process, by ulceration, or a surgical operation." (*See Cruveilhier's Illustrations of the Elementary Forms of Disease*, p. 7.)

Anthrax, or erysipelas carbuncle, resembles a boil (see Furunculosis) in being attended with gangrene of the subcutaneous cellular tissue, and, if one high authority can be relied on, certain processes of this texture within the skin. (*See Dupuytren, Clin. Chir.*, vol. iv., p. 155.) It is remarkable for constituting a circumscribed dark red or livid swelling, accompanied by burning heat, stiffness, and for soreness in the part; and occurring most frequently in parts of the body where the skin is thickest, and abounds most in those processes of cellular tissue which are described by Dupuytren as extending between its vessels. "Thus the nape of the neck, the back, the spaces over the scapulae, the sides of the chest, and the nates, are the ordinary situations of anthrax."

Anthrax differs from a boil not only in being of more obdurate size, but in being usually single, and lasting by several small apertures, whereas several boils frequently form together or occur in succession, and when one of these tumours breaks, it goes to by a single opening in its apex. The skin which covers the anthrax, and especially what lies over its centre, is of a deeper and more livid red colour than what is seen over a boil. The mortified cellular tissue is deeper and more extensive in anthrax than in a boil, in which it forms only a central nucleus or core. The surface of the tumour is flatter than that of a boil, which always rises in a conical shape above the level of the skin, while its base

does not penetrate so deeply as that of a carcinoma, which is a great deal broader than the more superficial part of the tumour. It is the nature of anthrax to produce gangrene and disorganization of the subcutaneous cellular tissue, and sometimes a destruction of even the adjacent muscles and deeper tendons; the mass of dead parts constituting frequently a slough of a lightish colour, part of which, mixing with the discharge, sometimes constitutes for it an appearance compared by Sir Astley Cooper to that of flax and water. Sometimes, however, the matter is bloody and viscid. Blisters, chiefly occur in children and young phlegmatic persons; the anthrax is mostly seen in subjects beyond the middle period of life, whose constitutions have been seriously impaired by intemperance or other causes.

The occurrence of anthrax on the lips is uncommon. Mr. Hunter, however, had seen the disease so situated. I have met with examples of it on the upper, side of the neck, in various parts of the bark, and on the nose.

Anthrax, or common carbuncle, is essentially different from the malignant pustule, so frequent in some of the southern parts of Europe (see *Gazette, Med. de Calcutta*, 1818, p. 104, &c.), in not being contagious. It differs also from pyoderma and malignant ophthalia (the carbuncle of Fernel and Celsus) in the same important respect. (See *Diagnos. Clin. Char.* 1818, p. 111.) This latter also regards the malignant pustule and festulant carbuncle as essentially contagious diseases, whereas simple anthrax seems to him to be so merely from stimulation of the processes of cellular tissue extending into the structure of the true skin. The correctness of this statement seems to be rather doubtful, because there can be no contagious species, whether benign or malignant, without a gangrenous disorganization of the cellular tissue, and the influence of constitutional causes. This is certain; but, whether contusions of the inflamed tissues, as alleged by Dupuytren, be the principal cause of gangrene, is a point which is far less clear. We find, indeed, that it is the character of carbuncular inflammations, first to produce sloughing of the cellular tissue, even when this may not be covered by any dense unyielding parts, though occasionally it afterward destroys all textures down to the vertebrae or scapula themselves. The gangrene, I should say, is independent of the constitution and confinement of the tissues affected.—C.]

[CARIES. The prominent feature both of absorption and caries is loss of substance through absorption. But, as Mr. Mayo properly observes, "caries is something more than mere absorption. When an abscess of the acetabulum against the acetabulum or vertebrae, the bones are gradually resorbed through; they are partially absorbed, but they are not caries. When, however, the focus attacked with hip, and the ulcer spreading in depth and breadth, reaches the bone, and then becomes excavated enormously, with the soft parts in the subjacent ulcer, the osseous tissue is not only absorbed, but truly caries. In caries, absorption is preceded by a change in the bone, which (with very few and doubtful exceptions) has a well-marked inflammatory character. The same modified mode during the progress of the absorption. There is further present an imperfect reparative action, which is shown in the narrow less partial growth of an osseous granulation from the abscessed surface. Of

these changes, the inflated condition of the bone is the primary and most important; the absorption is secondary and accidental. Absorption may be prevented by adding the iodine solution, or may, after laying begun, be arrested, and the crop of unabsorbable granulations transformed into a healthy reparative growth, if the case is of such a nature as to allow of the suppression of the inflammatory or specific action."

Mr. Mayo enumerates four kinds of caries: 1. *Simple*, when, in a person of sound constitution, a state of suppuration and protracted ulceration is set up in a bone through some accidental local cause. 2. *Syphilitic*, when ulceration is a specific periosal inflammation produced by lues. 3. *Strumous*, when the secretory ducts give origin to cysts. 4. *Malignant*, when the bones are affected in the extent of malignant ulcers. (See *Outline of Human Pathology*, p. 36.)

According to Mr. Mayo, syphilitic caries begins with inflammation of the periosteum, and "does not lead to much enlargement of the bone. The bone, commonly attacked in these cases, lying near the surface, can be observed to swell; the skin for instance, the skin, the clavicle, the cranial bones." The swelling by which syphilitic caries first manifests itself is called a "swell." It is an inflammation either confined to the periosteum, or involving, at most, the cortex of the bone. The periosteum becomes thickened, and is exquisitely painful. If the abscesses are divided down to the bone at this period, a thick, viscid, glairy matter, like honey, is observed in the cells of the periosteum, &c. The contents of the bone now gradually enlarge, or is thrown up in particles of porous bone, either formed by longitudinal grooves, or spongy and scab-like, filled with unabsorbable minute holes." The outer table of the skull, in several cases, generally has the appearance of being warm-colored. Mr. Mayo adds, that while the caries is making progress, the interosseous surface and matter forms below the skin, which afterward ulcerates. The skin, before breaking, has a livid colour, and afterward the skin around the ulcer has the same hue. The edges of the ulcer are excessively a little raised, its outline uneven, and the granulations irregular, and covered by a viscid, ash-colored secretion. A probe readily passes through the soft and gritty texture of the bone. The continuance of ulcerated areas and squamous eruption, or other disease of the skin, generally leaves no doubt of the nature of the caries. Sometimes, however, the latter exists alone. (See Mayo's *Outline of Human Pathology*, p. 40.)

Mr. Mayo is unacquainted with any essential difference in the appearance of cancer bone in some forms of scrofula, and in the period more dependent upon lues. "Less pain, less general inflammation, and a smaller extent of surface attacked, the absence of other symptoms, and the general physical appearance of the patient (he adds) afford a strong presumption of the scrofulous origin of the disease." (Op. cit. p. 41.)

The instances of traumatic caries noticed by Mr. Mayo are those from lipa and cancer (p. 42).—C.]

[CATARACT. PROBABLY DOUGLAS has succeeded in restoring sight to a child affected from congenital cataract on both eyes by the operation of becoming the lens. The child was three years of age.

Dr. McClellan has been very successful in the cure of cataract, and has performed extraction 72 times, chiefly for the least variety. In capsule and lenticular cataract, he relies upon simply excising a portion of the anterior capsule with a curved needle, and avoids disturbing the vitreous humor, or even dislocating the lens. He has had extensive experience in making an artificial pupil, having repeated this operation very frequently with success.—*Ransom*.

[CLAVICLE. Dr. J. C. Watson, of Boston, has performed the resection of the clavicle for osteosarcoma, but without the success which attended the operation of Dr. Mott, and its repetition recently by Mr. Travers.

Dr. McClellan, of Philadelphia, has successfully removed the clavicle and scapula for the same disease, and the patient has recovered. Dr. Munsey, of Cincinnati, has also successfully accomplished the removal of these bones in a case, the particulars of which promise great interest. (See *Amer. Jour. of Med. Sciences* for 1875).

Dr. T. D. Muller, of Philadelphia, has removed a part of the clavicle at its sternal extremity, including a portion of the sternum, for cancer of these bones. The best tips left at this important point of articulation has been fixed by a fibro-cartilaginous structure, so that, six-eight weeks after the operation, the motions of the upper extremity were perfectly restored.—*Ransom*.

[CLUB FOOT. In the article Tendons, Mr. Cooper has only made a brief reference to the new operation of dividing the tendons for the cure of talipes or club foot, and for the removal of other deformities; and in the *Achilles* I find the following article on the subject.

[CLUB FOOT. In the article Tendons I have noticed the operation of dividing the tendon of Achilles as a means of restoring the foot to its proper position in certain examples of this deformity. A great deal has been published on the subject of machinery for club feet; but, as Dr. Duguytren justly observes, the history of such cases was left very defective in consequence of no anatomical examination having been made of the parts affected. In the most frequent congenital distortion of the foot, termed by the ancients *varus*, the point of the foot turned inward, and the dorsum downward, so that the patient walks on its inner edge, and sometimes even upon the dorsum itself. The second, much less frequent variety is that called *valgus*, in which the foot is turned outward. There is also a third variety, in which the point of the foot is drawn backward, and the position of the whole foot is so reversed that the patient walks mainly upon the instep. Dr. Duguytren looks upon a dislocation of some of the bones of the tarsus, together with a subsequent change in the arrangement of the ligaments and tendons, as the essential cause of the deformity. All the external appearances of club foot were well described by Scarpa; but, according to Dr. Duguytren, no writers have hitherto attended to the affection of the tendons of the limb and its atrophy. "The deformity (varus) may be restricted to one foot, or extended to both. In the first case, if the instep be examined shortly after birth, the affected foot will usually be found much smaller than the other, but the two limbs are of the same length. When both feet are implicated, they are, in general, equally developed. In proportion as the time from the period of birth becomes longer, the atrophy becomes more and more evident, and the cause of

it is very applicable. In fact, the child, from inactivity, as it were, bears upon the sound foot, on which all the weight of the body is thrown. The result is, that its nutrition is more active; while the deformed foot, remaining comparatively inactive, must, on the contrary, dwindle away.

"But this atrophy is of two kinds, which have hitherto been confounded, though they should be discriminated: 1. Atrophy, according to the diameter of the limb; 2. Atrophy according to its length. The first kind chiefly affects the muscles, and hence the weakness and weakness of the limb; the second extends both to the muscles and the bones, but its action on the skeleton is the most serious and important; for the atrophy of diameter may always be removed by exercise of the muscles when the club foot has been rectified, while nothing can correct the shortened state of the limb." Though the shortening of the muscled and tendons is generally less in degree than that of the bones, yet it seems to Dr. Duguytren that it should be taken into consideration. "Thus (says he) the tendon of Achilles, at the age of twenty, has lost so much of its length that, even after the natural direction of the foot has been restored, the patient, in order to be able to lean on the ground, is obliged to wear a high-heeled shoe." Hence Dr. Duguytren insists on the importance of beginning the treatment of club feet very early, in consequence of the greater facility of the cure. In a very young infant, the foot may be rectified by the mere hand, and without pain; but at the age of ten or twelve years, machinery becomes necessary, and at a later period it fails, for nothing will then restore the length of the limb, nor even its shape and complete functions. (See *Duguytren, Clin. t. iii., art. 6*.) Occasionally a club foot undergoes a spontaneous cure, of which an instance is recorded by Dr. Hall. (See *Reperoire d'Anat. et de Physiologie*.)

The cure of club feet by division of the tendon Achilles, in cases otherwise inextinguishable, is one great improvement in modern surgery. Indeed, the division of other tendons for the relief of the permanent contraction and shortening of muscles is now occasionally practised with decided success. (See *Tendons*, p. 40.)

The novelty of this subject, and its importance to the profession, as well as the attention these operations have received in America, require a much fuller notice than is here given. The numerous examples in which maiming and lameness have been repeated in various congenital and acquired deformities, both in Europe and in this country, have created a new specialty, which has received the name of *Orthoplastic Surgery*, and one which is deservedly attracting a large share of attention both from the profession and the public.

The original suggestion of curing woe the tendon Achilles in club foot is due to Thomas, a German physician, and in 1794 it was successfully performed by his direction. Mr. Charles is [200], and Saraceni in 1812, repeated it in Germany with the same success. The late Dr. Dupuytren, presented it in France in 1822, but, though successful in the end, the cure was so long delayed, and attended with so much difficulty and danger, that his countrymen disapproved its repetition, and for the time the subject seems to have been everywhere abandoned. Indeed, when it is recollected that the frequency of this deformity in every country was increasing, and its victims included some of the most distin-

gished men among the European aristocracy, of whom were Prince Talleyrand, Lord Byron, and Sir Walter Scott, and that, for the removal of these deformities, no effort was made, we have the most conclusive evidence that no confidence existed in the safety or propriety of the operation. Anticipation of the suffering neither was the only restraint which was alluded to, and this was accordingly performed in numerous instances. An eminent surgeon in New-York ascribed the loss of a gentleman for club foot as early as 1834.

In the year 1834, Dr. Stearns, a celebrated German surgeon, revived the operation, dividing the tendo Achillis by a subperoneal incision; and, having been successful in two cases of club foot without any untoward symptom having followed, he soon after published an account of the cases and their results. Among the earliest of his imitators were Dr. Dickson, of North Carolina, in 1835, Dr. N. R. Smith, of Baltimore, in 1836, and Dr. William Denold, then of Hanover, but now an eminent surgeon in the city of New-York, in 1837; and the latter having been the first to publish an account of his operations in the United States, which he did in the *American Journal* for May, 1838, he has probably had more extensive opportunities than have fallen to any other surgeon, either in the Old or New World. Dr. Denold has now performed more than 400 operations in club foot, and divided more than 1500 tendons in Stearns's plan of subperoneal incision.

His extensive opportunities and experience have proved, 1st, that the disease formerly supposed to be consequential upon wounds at tendons are wholly arbitrary; 2d, that the mode of a divided tendon takes place readily and infallibly, however the cut ends are separated by the restoration of the heel and foot to normal position; 3d, that a large proportion of the deformities called club foot, including congenital cases, regarded as hopeless malformation, can be cured by the division of the several tendons upon the contraction of which the deformity depends, and by means of subsequent mechanical management. "In all his experience he never saw an unsuited tendon follow his operations, nor has he had a single example of aneurism or any other troublesome sequel."

In the last edition of the *Institute of Surgery* by Professor Gibson, of the University of Pennsylvania, will be found a highly interesting and discriminating account of the nature, causes, varieties, and treatment of club foot, written for the work by a son of the author, Dr. Charles Bell Gibson, at Baltimore, a young surgeon who gives promise of early eminence in his profession. From this article it will be seen that the disease may be either congenital or accidental. The former are ascribed by him to some malformation of the foot in utero, and the latter may result from fracture, laceration, apoplexy, ulcers, or partial paralysis.

He enumerates five varieties of club foot, viz, 1st, *Pes equinus*, when the patient walks on the toes or the metatarsophalangeal articulation; 2d, *Varus*, in which he efforts upon the outer portion of the dorsum of the foot; 3d, *Valgus*, in which the limb rests on the inside of the foot; 4th, *Phalangial*, in which the patient struts on the distal face of the second and sometimes bones of the tarsus, the toes and metatarsal being turned under the heel, and the fore part of the foot lies with the axis of the limb; and, 5th, *Talus*, in

which the heel being directed downward, the dorsum of the foot is applied in front of the leg.

The varieties of club foot have been thus more intelligibly defined, viz., *Talus equinus*, abnormal extension of the foot; *Talus varus*, extension of talus, abnormal flexion; *Talus valgus*, extension with adduction; *Talus valgus*, flexion with abduction. The other varieties will be found to be but complications of these, or groups or lack directions, though belonging to one or more of these feet.

Of these varieties the most systems would seem to be a combination of the first and second varieties, and each of these five varieties, though easily recognized, will be found more or less complicated by the greater or less extent of displacement, diagnostic of each. And when they depend in whole or in part upon muscular contraction, a number of tendons other than those of the gastrocnemii will be found to be involved. Cases of double club foot are often found among congenital examples.

In regard to the treatment of club foot, Dr. Gibson, beginning with the bandage, traction, and shoe employed for the purpose by Hippocrates, traces down to the present and the multiplied surgical and mechanical methods to cure these deformities by mechanical apparatus, of which, indeed, both he and his distinguished father were disposed to speak with much fervor, and they express a doubt as to the possibility of benefit derived in successful cases from the removal of the tendons, when the apparatus is not provided in the subsequent management; and they seem inclined to ascribe the cure to the apparatus alone, which they regard as in some cases a competent remedial agency in the removal of these deformities. The apparatus of Dr. Huber Chase, of Philadelphia, is spoken of as having been successful in removing the deformity of club foot, in no different varieties, by mechanical means alone.

The principles upon which Dr. Chase's apparatus operates are nearly the same which have been from time immemorial regarded and practiced, inadequately, however, with but little success except in uncomplicated cases, or when applied soon after birth, in the congenital variety. For the accidental form of talipes, or when the case is in an adult, the utility of any form of retentive apparatus has been more than doubtful, and in cases reported by Dr. Chase, have appeared to be that such deformities may be removed by the modification of mechanical means, which, alone, he believes, possesses the power of greater superiority than the very complex apparatus formerly employed. His experience thus far has been highly satisfactory; and some of the cases reported in the *American Journal of Medical Sciences* and other periodicals, while they reflect great credit on his science and skill, they certainly render it probable that a large proportion of these and other deformities, for which apparatus and tenotomy are coming in vogue, may be better removed by mechanical means than by the use of the knife. Still, however, it must be remembered, even by those who have marveled themselves against the innovations of antiseptic surgery, that there are varieties of club foot for which the division, not merely of the tendo Achillis, but of the tendons of the anterior and posterior tibial, peroneal, &c., will be found indispensable as preliminary to the successful employment of any apparatus; and, as in all cases when the cause

tion of tertiary, precisely similar mechanical strains are demanded as when these are originally called on, there need be no strife between the advocates of either method other than a laudable ambition to excel in their success by removing the deformity, and restoring the limb to usefulness and utility. No enlightened or reputable surgeon will be indolent enough to practice the operation in any case where mechanical means hold out a rational hope of success without it; nor should any such beautiful devices, tendons or muscles, be any extent demanded, for the removal of such deformities, after the multiplied and satisfactory proofs before the profession of the safety and benefit of these operations, even in cases to which no mechanical apparatus could be possibly be adapted, or in which the attempt has been fairly and fruitlessly made.

In Europe, especially has been very frequently performed in these cases by Dieffenbach, Day, Bruns, Roux, Lispen, Whipple, Koenig, and others; and in this country, since it was introduced to the profession by Dr. Denold, it has been repeated by surgeons in almost every part of the country. Professor Mott has returned from his European tour and temporary foreign residence so impressed by what he witnessed while among transatlantic surgeons, that he has projected in New-York an orthopedic institution, devoted to the reception and treatment of all the deformities and malformations for which this new department of surgery is adopted, and which he designs shall be a school for teaching this specialty, and widely diffusing the advantages throughout our country by clinical lectures and published reports of cases. Dr. Denold, meanwhile is almost daily receiving patients in the same city from various parts of the United States, by which it is ascertained that the cases of club foot are vastly more numerous than was ever imagined until the method of cure was discovered. As this profession has devoted himself almost exclusively to the department for a number of years, and is now engaged in lecturing on the subject before the College of Physicians and Surgeons in New-York, I would refer to an elaborate paper on the subject, in the N. Y. Journal of Medicine and Surgery, which is remarkable for its eminently pathological and practical character. It may be found in the number of that quarterly for January, 1861.

From Dr. Denold's valuable publications on this subject, I must content myself with a brief analytical summary of the theory and practice. He divides club foot and knotted deformities into three to the same extent, a disturbance of the equilibrium between antagonistic muscles, and he examines the various opinions of other surgeons on this topic at length. At the date of the publication, 1860, he had been consulted in 167 cases, of whom 95 were males and 72 females. In 93 both feet were affected, in 41 only the right foot, and in 31 only the left foot. Of the 167 cases, 135 were congenital. Of these, 115 were otherwise well formed, 11 had some other congenital defect, apparently independent of club foot; in two the whole extremity, femur and tibia, were essentially short; in the rest half the length of the other sound extremity; one had a heavily scrooped squinted; one had the toes of the club foot grown together; and one had an additional thumb, that is, two thumbs on the hand corresponding with the club foot. To these and similar statistical information collected with great discrimination by Dr. Denold, he has dis-

gently inquired into the properties of hereditary cases, which in almost every instance is on the father's side, perhaps for the reason that club foot females seldom marry; and Dr. Denold reports a single example having occurred in the progeny of a childless mother whose infant had the maternal deformity.

Of the 167 patients, 53 being females with foot-club, furnish for the statistical inquiries 320 club feet; and of these 320 were of the species called talipes varus, which is vastly the most frequent form of the distortion. Only 11 were of the species called talipes valgus; 17 were of the form named talipes equinus; and but one of the species called talipes calcaneus, and it existed in both feet, which merit to the cured variety. Dr. Denold suggests for this last variety the name talipes equineus, for the reason that it resembles the position of the foot in the stumps in the act of riding.

In respect to the treatment, we have here a corroborated, no doubt, accurate investigation of the cases which may be cured by mechanical means alone, and those in which surgery is either necessary or advantageous. Dr. Denold is far from advocating the indiscriminate division of tendons by the knife in every case of club foot, and still less does he approve of the practice, sometimes resorted to unnecessarily, of putting a number of tendons. He inquires that in a great majority of cases the division of the tendo Achillis is the only cutting which is demanded; especially in young subjects, though he admits that sometimes, in older subjects, the cure may be facilitated by dividing, in addition, the fibula anterior and posterior, the flexor digitorum, and sometimes the extensor digitorum; and in yet rarer cases, the peroneal, and that, in degeneration of long standing, one may possibly be aided by cutting the ligamentum plantare. Still, in nearly all cases, it is better only to divide the tendo Achillis, and then attempt the cure by extension, at least postponing any further division of tendons until, in the progress of the treatment, it becomes absolutely imperative.

Our space will not permit the introduction of the exhaustive list of the modes of operation of surgery, or the resources by which it is sustained. Nor can we enter upon the details concerning the instruments, or the manner of using them, either for dividing the tendons, or for supporting and extending the limb, in the subsequent mechanical treatment. It must suffice to remark that Dr. Denold is opposed to the immediate extension of the foot by any apparatus, but prefers waiting two or three days after the operation. The apparatus of Stinson has been suggested by Dr. Denold, and he greatly prefers it to the mould of plaster of Paris over the deformed foot described by Guerin. He also employs the shoe of Scarpa.

Dr. Denold has divided the muscular tendons in a case of contraction of the ligament which was essentially relieved, but his results disturbed this just ordered plan for the success of extending. He also, however, writes in contradistinction of the upper extremity, we can never be so successful as in the lower and foot, though he has offered considerations of the whole by dividing the biceps, and those of the wrist and fingers by cutting the flexors. The difficulty in these cases arises mainly from the impossibility of simultaneously availing ourselves of mechanical means of support and extension, while in contradistinction of the lower and ankle-joint we

money will seldom fail, it being so easy to adapt the apparatus to the lower extremity.

Dr. Denold speaks favourably of the division of the *sternoclavicular* tendonless for very thick, but expresses himself doubtfully of M. Guerin's operations on the muscles of the back for lateral curvature of the spine. The success which has attended this operation, however, in the hands of Guerin, since this paper was written, would seem to promise much for it in future. It is worthy of remark, however, that Dr. Denold suggests the division of the muscles of the eye in strabismus, and avows his conviction that, like club foot, it depends on spasmodic muscular action, and he duly hesitates in recommending the division of the muscles of the eye from a doubt whether the slight inconvenience would justify such an operation. At the time this paper was written, Stromeyer had, in like manner, made the operation, but the operation had not then been performed.

Dr. Denold's paper concludes with a detailed narrative of thirteen cases, with their treatment, of which we have only room for an extract from the summary, by which we learn that of the 220 cases, the tendo Achillis alone was divided in 163, and in seventeen, this, with other tendons, and the *aponeurosis plantaris*. In three cases the operation was repeated on the tendo Achillis. All the eleven cases of valgus, and the only two of calcaneus, together with forty-two of, *varus*, were treated by mechanical means alone, without tendotomy.

For other muscular contractions, Dr. Denold has divided 1 *spino-plantar* tendonless, 1 *iceps* tendon, 1 *brachio-caps* tendon, 1 *flexor carpi ulnaris*, 1 *palmaris longus*, 1 *flexor digitorum* tendon, 4 *flexor tendons* of separate fingers, 1 *peroneus*, 4 *iceps* tendons, 7 *antimembranosus* and *scaphoideus*, 5 *extensor tendons* of separate fingers, 4 *flexor tendons* of separate toes, besides a number of times different portions of fascia and aponeuroses. In all these instances the disease was, effected subcutaneously, and the external wound healed by the first intention.

Dr. Munier, of Philadelphia, has also acquired great and merited reputation in orthopedic surgery, and his opportunities have been extensive. He has already treated more than 200 cases of club foot, either with or without tendotomy; 13 cases of very thick, 4 cases of contracted elbow, 15 of contracted fingers, 32 of contracted knees, 3 of rigid ankyloses, and 89 of strabismus, and has had extraordinary success.

The extent to which tendotomy and myotomy has been practiced, especially in Paris, may be estimated by an example recently published by M. Jules Guerin, of Paris, in which he made a subcutaneous section of forty-two muscles, tendons, and ligaments on the same person, and at one time, for the cure of a general atrophic deformity; and yet, in this and similar extraordinary instances, no unusual results have followed.

M. Guerin, who is the celebrated filius of the Gazette Medica, has also applied the principle of division of tendons to remove lateral curvature of the spine, and many cases, both in private practice and at his orthopedic institution near the Bonaparte, attest the success which has crowned his efforts, conjured as they are with pure science and consummate mechanical skill.

In Duguesne's Amer. Med. Intelligencer, for May 1st, 1849, there is an article by A. G. Wal-

ter, M.D., of Pittsburg, by which it appears that Dr. W. has greatly improved the convenience of a patient suffering under extensive distortion of the lower limbs, by dividing the tendons and muscles of the hip, the knee, and the ankle. He first divided the attachment of the adductor longus and gracilis muscles, with the fascia lata on each side, by introducing the knife about an inch below Pott's ligament, and then extended the foras, which was before impossible, so as to cut the tendons of the sartorius, gracilis, semi-tendinosus and semitendinosus in each limb, and thus was enabled to give maximum to the knee, which had been previously fixed, and, lastly, he divided the tendo Achillis and portions of each foot, for the removal of that variety of club foot called valgus. The power, for the division of the peroneus muscles, to go below the malleolus externus. All these tendons were treated subcutaneously, making five incisions through the skin by dividing the muscles and tendons on each extremity. Subsequently an elaborate mechanical treatment, first, at the knee of the support, his stitches had increased in value, and with the aid of crutches he could walk very well, and there appeared every prospect of complete success, attending the operation, though the case was an unfavorable one, being to the very existence of constitutional disease being child hood, this appears still after several months which accompanied it, and the number of years in which locomotion of the limbs had been lost of the epidemic. The complete removal of the deformity of the several joints, and the fragments of the patient by allowing the extreme necessary to his restoration, of themselves, with the operation to great merit, who possesses very creditable success, even if to further experiment should be attained.

Dr. Allen C. Post, of New-York, has treated with success a considerable number of cases of club foot and other analogous deformities. In one case of complicated deformity, he divided the tendo Achillis, the plantar fascia, the muscles of the tarsus metatarsus and peroneus, and of the flexor longus pollicis polvis, the two external tendons of the toes, the peroneus longus, the semitendinosus and semitendinosus, the gracilis, the adductor longus, and the lesser saphenous branch of the right side; also the greater saphenous and adductor longus of the left side. Dr. Post has constructed some ingenious and useful modifications of instruments, and the treatment of these deformities.

An invaluable treatise on the subject has been published by Dr. Little, of London, on the nature of club foot and analogous deformities, including the treatment both with and without surgery, and in this work the young orthopedic may refer for detailed practical instructions, illustrated by numerous cases. Dr. Little has himself a series of congenital talipes, and has long practiced the operation of tenotomy on his own feet, and had only been directed by the results of Delpech's case, and the advice given by his professional brethren. Having secured the success of Stromeyer, he proceeded to Haver, and became the patient of that eminent surgeon in 1835, by whom his own deformity had been cured. Since then, during his stay on the Continent, Dr. Little has been repeating the operation on others, and on his return home he had the honor of introducing the Stromeyerian method into the British metropolis.

M. Rouvier, of Paris, and Dr. Whistler, of

London, had anticipated Dr. Little, according to the plan of the former gentleman. Mr. Wiggles having thus devoted the tendo Achillis as early as May, 1806. But Dr. Little was the first British practitioner who practiced the Stromeyerian method of cure, his first case in London being performed February 1828, 1837.

It seems, however, that Dr. Thomas Inglis, of Glasgow, as early as 1832, guided only by his sensations and his vehement desire to relieve himself from the deformity, he being afflicted with congenital talipes equinus, boldly divided the tendo Achillis of his right leg. Dr. Inglis was at that time a young man, and had not yet commenced his medical studies; of course, he rudely cut down without regard to the skin, fascia, and tendons, having no knowledge of the subject, but desperately determined to remove his lameness, even at the risk of his life. "The hemorrhage so alarmed the family that he was placed under surgical treatment, and the foot enlarged to a state of extension, the edges of the divided tendo-achil closely in contact, and he being prohibited from walking until the union was complete. No untoward circumstances delayed admission, but the deformity was, of course, unchanged. Thus he remained until 1837, when, he went to London, and placed himself under the treatment of Dr. Little, by whom the same operation was repeated on the 11th of August, and in three days, the puncture having cicatrized, Stromeyer's foot-board was applied for extension, and in a few days the foot was as much bent at the middle-joint as that of the opposite limb, and Dr. Inglis is at length perfectly cured of his deformity.

So frequently have patients suffering from club foot ascribed their deformity "to the cord behind the heel," that nothing but the imaginary danger of wounded tendons could have prevented the surgical expedient now so extensively adopted. Indeed, the current misapprehension of surgeons against cutting the tendo Achillis has often been necessary to prevent other besides Dr. Inglis from making the experiment on themselves, so cautious have they been that their deformity depended on this "cord behind the heel."

Among the varieties of cases related by Dr. Little as having been treated by him, will be found congenital and non-congenital examples, of one foot or of both feet, and existing either as *T. equinus*, *T. varus*, *T. valgus*, or *T. calcaneus*, with and without the complication of these varieties. In numerous examples of *congenital talipes* flat, we have existing in the same patient the analogous deformity of club hand, and which is found to depend on similar muscular contractions, the flexors and pronators of the hand being affected like the extensors and abductors of the foot. So, also, in all other congenital cases of club foot and club-hand, congenital squinting and congenital stammering are found to be simultaneously present, and which may be ascribed in such examples to the increase of the sympathetic, or the decrease of the voluntary motor power of the ocular and laryngeal muscles. And it is a remarkable fact, that even some cases of non-congenital club foot are complicated with squinting.

In respect to the causes of club foot, a variety of conflicting opinions exist in the profession; the most probable of which is, that it depends in all cases upon spasmodic muscular contractions, and may therefore originate from any cause capable of producing the spasm, whether

or applied before or after birth. This pathology of these deformities will explain the fact that it so often occurs after birth and at various ages, while these non-congenital examples are found to possess the same inflexible and essential peculiarities as the congenital affection, advancing often to the same grade of deformity, and removable by the same means. The better knowledge we now possess of the morbid anatomy of these deformities, and our experience as to the causality both of the congenital and non-congenital varieties, prepare us to reject many opinions as to their etiology, which have been adopted for want of these guides by those who have hitherto investigated the subject; for nothing can now be ascertained than that the cases which are known to have originated during fetal life, and those which have occurred long after birth, are identical in their nature, and are dependent on some common cause.

In regard to congenital cases, there is nothing unphilosophical in admitting the ancient opinion that a severe fright to the mother during pregnancy may be one of the sources of club foot; for a violent mental impression made upon the maternal circulation may so disturb that of the fetus as to affect the brain and spinal chord of the infant, and result in spasmodic contraction of various muscles, leading to different kinds of deformities. This theory, which ascribes the deformity to some cause resident within the organization of the fetus, is incomparably more plausible than that which ascribes it to mechanical pressure, or the entanglement of the limbs *in utero*, especially as these deformities have been so often found during early periods of fetal life, when the pressure of the liquor amnii would protect the limbs from being acted on by these mechanical causes.

The first appearance of non-congenital talipes is frequently observed during dentition, or after convalescence from some infantile disease, especially of spasmodic character. The loss of the use of the limb or limbs is at first often ascribed to paralysis or to general debility; but, as the child gains strength in every other part of the frame, one or both limbs are found to be drawn up, and we have *T. equinus*; or a turning in at the toes is observed, and *T. varus* is present; or, as in other cases, *T. valgus* or *T. calcaneus* may result. Dr. Little has observed these several forms of club foot, the history of which was preceded by infantile diseases such as are here stated. And he gives cases in which talipes has been thus originated by disturbances of the organic system of nerves, not merely in infancy, but at later periods of life, even after the age of puberty. He cites instances of hysterical young women who had previously enjoyed the perfect use of their limbs, and yet, through spasms of the gastrocnemii, and anterior and posterior tibial muscles, they have been ever after afflicted with club foot, having all the characteristics of the congenital form.

Dr. Little's doctrine is, that any cause, or other paralytic or spasmodic, by which the equilibrium between different sets of muscles that are mutually antagonists is disturbed, may produce club foot. Other disorders more or less resembling club foot are often produced by the contraction of the limbs or elevation, or by too long confinement of the limbs in a particular position, or, indeed, any agency which seriously disturbs the antagonism of the muscles. The adoption of this etiology will lead to a more rational treatment of all these

dislocations than the indiscriminate employment either of amputation or mechanical apparatus and bandaging, or both, however valuable these means may be regarded in the cases to which they are appropriate.

The plan of treatment in these non-congenital cases should be decided upon the principles of rational medicine and enlightened surgery; and such deformities call for as careful discrimination of the true pathological state as is demanded in other cases of organic or functional malformation. A case of talipes originating from paralysis of the anterior muscles of the leg, with, when it occurs after birth, precisely the same treatment as is adapted to paralytic affections in any other part of the body. Hence, when the flaccidity results from active, permanent, and involuntary contraction of the muscles of the calf, the attention of the surgeon should be directed to the central organs of the nervous system, the brain and spinal cord; or in other cases, he will find the incident and reflex functions of the nervous system which have disturbed the equilibrium of the muscles of the foot to the eklyso-poetic or other visceris, and medicate accordingly.

Dr. Little's work, because of his interesting these views at length, is the more worthy of con-

sideration. So, also, he discriminates clearly between the cases which can be cured by surgery and means alone, and those in which treatment is demanded in order to render any such apparatus available for permanent benefit. I commend for the surgical reader to his work as one which will amply repay a perusal.

Dr. Hester Gross, of Philadelphia, is generally supposed to be the practice of indiscriminate amputation in club foot, now becoming an epidemic in this country. He believes that a large majority of cases are curable by treatment alone (1841), and are carefully detected, without the aid of the knife. His instrument for the primary treatment of tarsus and talus, which is a new structure and very simple, is described and figured in a paper published in the *American Journal of the Medical Sciences* for January, 1841, in which the author has given the results of a number of cases. He contends, in his lecture on dislocations, that the system of treatment advocated by him is capable of restoring the foot to its normal shape 'with more certainty, greater ease to the patient, and in less time than any of the methods of extirpation practiced also hitherto.' He also contends that there remains less disposition to relapse. —[Editor.]

D.

[DEFORMITIES. Dr. Mutter, of Philadelphia, has the merit of having been the first in America to perform Dieffenbach's operation for removing a deformity of the mouth. (See *Amer. Jour.* for 1837, No. 40.) And in the last number of the same journal, the same surgeon reports a case of rigidity of the masseter muscle relieved by an operation. In this operation Dr. Mutter has the priority, although it has since been performed by Dr. Cammahan and Dr. Schmidt, of New-York, and also repeated in Europe. Dr. Mutter has succeeded in these cases.

In the *American Journal* for July, 1842, Dr. Mutter has published an original operation for removing a hideous deformity occasioned by a tumour, illustrated with plates, and which will be found to be highly creditable to his skill and science.

Dr. Pincoast, of Philadelphia, has successfully operated upon a number of cases of immobility of the lower jaw, with extensive adhesions following mercurial ulcerations of the cheeks and gums, and accompanied by frightful deformities.

Dr. Mutter has also reported in the *American Journal* for 1842 a case of deformed leg, in which resection of the bone was preferred to amputation, with the happiest result. —[Editor.]

[DISLOCATION. An instance of a collocated dislocation of the sternal end of the clavicle backward is related by Mr. Tyrrell. (See *St. Thomas's Hospital Reports*, vol. i., p. 263.) It was caused by the fall of a heavy mass of earth, which drove the sharp end of a pickaxe against the chest. When the finger was introduced into the wound, the great pectoral muscle was found torn from the clavicle, and the fibres could be passed as far outward as the removed process, and inward to the trachea. The greater part of the intersternous cartilage remained in its place. There was emphysema below the clavicle and over the sternum, and difficulty of

breathing. The shoulders were brought back with straps attached to a lockboard, and the bone readily resumed its place. The place was brought forward, and bound to the side. The case terminated well.

Mr. Anstey Cooper informs me that the dislocation of the os humeri on the acromion at the hospital is most readily reduced by leading the elbow, putting the foot behind the neck, and then sustaining the force and of the humerus backward.

Mr. John Mandeville has published the case of a simple and complete dislocation of the scapula from the os scapulae and clavicle, having been upon the dorsum of the latter, without interference of the relations between the two bones, and without fracture of any of these bones. (See *Dublin Jour. of Med. Science*, vol. xij., p. 225, &c.) —[C.]

[Dr. George W. Norris, of Philadelphia, has published a case of complete laceration of the knee without fracture, in which the M. and M. ligaments were involved, for which see *Amer. Jour. Med. Sciences*, vol. i., new series, p. 448.]

Dr. J. Waigon, of New-York, reports an interesting case of dislocation of the patella on its axis in the N. Y. Med. and Surg. Journal for 1841, together with observations on the case of a valvular elongation, which is also referred to in the *Cyclopaedia of Anatomy and Physiology*, published in Great Britain.

Dr. Latham reports, in the *Amer. Jour.* for 1837, a case of a tumor which could dislocate the shoulders at pleasure, and was in the habit of exercising this power of dislocation when he wished to avoid any laborious or disagreeable movement. The location was always effected downward and toward, and was readily produced by the voluntary contraction of the musculature, never by any active aid from the hand. It was in every case readily reduced in the most

way; and although he was able at once to see the fault at his work, yet, as he was directed by the surgeons who were called to him to wear it in a sling for a few days as a measure of precaution, he was wont to avail himself of this course, and thus incurs the inconvenience. This must be superadded, therefore, to the list of trivial diseases; for, although self-induced, he was not able to effect reduction without surgical assistance. The case, however, must be a very rare one, probably unique.

Dr. Gross has inserted a note, in his late Philadelphia edition of *Liver's Elements of Surgery*, on congenital luxation of the hip-joint, which, though rare in this country, has been witnessed by Druryton in twenty-six cases; and he found it to be hereditary.

Dislocations of the hip-joint, in which the head of the femur takes other directions than the four ordinarily laid down in the books, are often observed. Dr. William Parker, of New-York, relates an interesting case, in which the head of the

bone was found in the yermium. *Am. N. Y. Gazette*, vol. 4, 1841.

A NEW CASE OF LUXATION AT THE SHOULDER.

Professor Parker, of New-York, was called by Dr. K. Campbell, of Pittsfield, Mass., to see a patient who had luxated the right shoulder. He was twenty-two years old; good constitution; was at work at the time of the accident in a wheel-lathery. The luxation was produced by the handle being caught between the belt and drum while the machinery was in rapid motion. The hand was seized under the drum, being strongly yroned up to the head of the handle, seemed to have been strongly twisted; the capsular ligament was rent, and the head of the bone was left under the axilla; the continuity of the axillary ligament and the arm and forearm were lying diagonally across the thorax.

This luxation was reduced into the axilla, and then from this position the head of the bone was readily carried into place.—*Revue.*

E.

[**EAR.** Mr. Edward Cook has examined the temporal bones of five children, who died of strumous diseases of the thoracic and abdominal viscera in the Asylum for the Deaf and Dumb. In three instances, one or both ears near the seat of serofulous ulceration, affecting the tympanum and mastoid externus, with partial degeneration of the membrane tympani. In one case, the cavity of the tympanum, together with the mastoid cells, was completely filled with the thick, shaggy deposits of scirrhous, while a similar affection permeated the whole cancellated structure of the petrous bone. The ossicles of the ossicula were destroyed, but the bones themselves remained entire. In all the cases examined by Mr. Cook, the petrous portions of the temporal bones exhibited more than the usual varieties of size and shape. In some, the bone was so deformed in particular spots as barely to cover the internal cavity, while in others there was a preternatural osseous development. In one instance, the petrous part of a child twelve years old exceeded in size, hardness, and compactness of structure that of an adult. One malformation, discovered in two cases, consisted in a partial deficiency of two of the semicircular canals. Their extremities opening into the vestibule were perfect, but the central portions were imperious, or, rather, did not exist at all. In one case the scala tympani was terminated at its larger extremity by a long septum, which separated it from the tympanum, and occupied the situation of the membrane of the fenestra rotunda. With the exception of these malformations, and the serofulous affections of the tympanum already mentioned, which were probably of recent occurrence, no deviation from the healthy state could be discovered in either of the five subjects examined. The Eustachian tubes were pervious; the bones, muscles, and membranes entire and sound; the labyrinth was filled with their transparent fluid; and the auditory nerve presented no peculiarity. The chorda tympani existed in each of the cases; but the integrity of all its little filaments passing into the tympanum, and possessing a microscope for their dissection,

could not be vouched for. (*E. Cook in Med. Chir. Trans.*, vol. 41, p. 152.) In a case discussed by Mr. Daurympie, the aqueduct of the vestibule was large enough to admit a small probe; and, in a later examination of the ear of a child who died in the Asylum for the Deaf and Dumb, Mr. Cook could find no vestige of the fenestra rotunda on either side, the whole situation of the membrane being occupied by solid tissue. The temporal bones were accordingly large, though soft and spongy. The canals were extraordinarily capacious, and the Eustachian tubes three or four times larger than common. On one side, the aqueduct of the vestibule readily allowed the passage of a large needle, but on the other side the canal could not be traced through the bone, although its two extremities were more than usually expanded. In one tympanum separation had taken place. (*E. Cook, ib.*)—C.]

In the United States there have been few surgeons who have distinguished themselves by their success in the treatment of diseases of the ear. Deafness is a less frequent disease in this country than in Europe, but cases are nevertheless sufficiently numerous to deprive us of any justifiable excuse for the neglect which this subject has received from American surgeons. It is true that the reputation here of the methods of Krüner and other foreign writers have been much less successful than those transatlantic surgeons would lead us to hope. Still, however, there have been instances of similar success to those they report, and in sufficient number to encourage future efforts.

Dr. Cohen, of Baltimore, and Dr. Dix, of Boston, have for several years directed their particular attention to diseases of the internal ear, and in the investigation of the abnormal condition of the tympanum and Eustachian tube in cases of deafness. These gentlemen have employed condensing apparatus for administering the air directly through the Eustachian tube, after the plan of Krüner and others. By the air and also the water douche, these gentlemen have acquired great skill in the diagnosis and treatment of ob-

strations in the tube and upon the tympanum. For the treatment of nervous deafness, the douche of acetous and sulphuric ether has in many instances been successful, but the proportion of cases benefited by the douche in this country is very much less than stated by Keen.

There is reason to believe that, in minor affections of the ear, accompanied by temporary deafness, very great mischief is often done by the earpick, employed empirically by the patient himself. The little finger on each hand has been called the ear finger, because of its adaptation to the office of clearing out obstructions in the external ear; nor should any smaller or round instrument ever be introduced except by a surgeon, who has his eye to guide him, aided by a speculum auris. The introduction of ear-picks and pins into the external ear by patients is among the frequent causes of irreparable deafness. So, also, stuffing the ear with cotton, either with or without oil and other medicaments, is to be deprecated by all who would not hazard the loss of this important sense of hearing. The fibres of the eardrum often become interperforated with the morbid secretions in the meatus, and find their way to the tympanum, and are not easily removed. Hence wool should be substituted in such cases, as not liable to this objection.

In the treatment of furuncle, however, which is often genuine otitis, and requires active depletion, local and general, suitable discrimination is demanded. But in those cases depending on a local morbid sensibility, without evident inflammation, it is common to stuff into the meatus a plug of cotton or wool moistened with oil, with or without a mixture of iodoform. This practice, when not absolutely ignorant, is never useful. If it be expected to reach the membrana tympani with the medicated oil, it should be poured into the external ear until it is full, which may be known by the cessation of the escape of bubbles of air from the surface of the oil after the ear is filled. A piece of wool may then be introduced into the meatus. This method of introducing olive oil, or the oil of almonds, into the ear, will often relieve deafness, when ascribed to be dependent on hardened cerumen. The injection of the oil, or of warm water, which is better, is greatly preferable.

In those examples of deafness arising from a deficiency or absence of cerumen, and, indeed, in cases of serous deafness, and all others in which there is a want of sensibility in the organ, I have found early and permanent benefit by the kerosene mixed with oil of almonds, in the proportion of one part of the former to three of the latter. This mixture should be introduced upon a cannula held perpendicularly to the tympanum, and, with suitable discrimination in the cases, will never do mischief, and often effect a cure. The reader will find in the article on this subject in the Dictionary many valuable matters, to which I have here prefixed what is important in Mr. Cooper's last edition.

Dr. Murray, of Cincinnati, has operated, by perforating the membrane of the tympanum, for deafness, accompanied by a closure of the Eustachian tube, in six cases. Only one of these patients was restored by the operation. In the other five cases, the deafness, in all probability, was independent of the closure of the tube, although this was not ascertained.—[Rex.]

[ECTROPIUM. Jussieu describes a plan, which has been adopted by Jaeger himself, and was practised a hundred years ago by Platani

(*Ann. Chir.*, 4 582), and even recommended a century before this author by our countryman Bonister. Heister and Dierle state a still more circumstantially. (See *Mémoires sur les Op. de l'oeil*, vol. 2, p. 782.) It consists in detaching the eyelid from the cheek, by a superficial ridge, at every point excepting the angles, by introducing a sharp-pointed, double-edged knife through the conjunctival surface, near the nose angle, bringing it out through the skin, and conveying it across to the outer angle. A portion of the thickened conjunctiva, or a triangular piece of the lid, may be first removed, if necessary. The detached lid is then to be accurately fixed in contact with the globe, and the skin of the cheek drawn towards the eye, and kept in that position with adhesive plaster, compresses, and bandage. (Hendrick, *op. cit.* p. 695.) Dieffenbach makes an incision through the skin and conjunctiva nearly parallel to the edge of the lower lid, beginning two or three lines from the angle, and terminating at the same distance from the other. It is one line from the edge of the lid at its two ends, and two or three lines in the middle. He turns up the small flap of skin, and dissects through the lid to the conjunctiva, which he divides to the extent of the external wound. With a hook he draws the external margin of the divided conjunctiva into the wound of the skin, and keeps it and the ligaments together with sutures. (See *Clin. Chirurgie*, par Dr. W. Dieffenbach, *Zeitschr. Fests.*, 4, tom 1, p. 118, fig. 127, Berlin, 1837, also *Archiv. Anat.*—C.)

[EMBRYOTOMY. In the Philadelphia Practice of Midwifery, by Dr. Meigs, an unusual case is reported, in which the practitioner employed a peculiar trocar and forceps for the destruction of the foetus, which the surgical reader will find to be of great practical importance. This earlier patient has been twice referred to the Gynaecian section by Dr. Gibbes from Dr. Meigs's operation of embryotomy, and the case will be found under the appropriate head in this Appendix.—Rex.]

[EMPHYEMA. In the Amer. Journal of Med. Sciences, Dr. Pennington, of Philadelphia, has published a paper on emphysema, in which he describes a new plan of treatment, the success of which is the case reported is the last proof of its utility.—Rex.]

[EPISIORAPHY. Professor Gittings has published a monograph on the subject of entosis in the external labium of the female, in which may be found in the American Journal for 1845. Since then the operation has frequently been reported in this country with success in proclivous cases. Dr. Ewe and Dr. Dugas, of Georgia, have both practised it successfully.—Rex.]

[EPISPADIAS. Dr. Matter has cured two cases of this disease by the urethral operation. Dr. Meigs, of Virginia, has lately published a paper on this malformation, including hypospadias, which is of an eminently practical character. It may be found in the Amer. Journal of Med. Sciences for July, 1842.—Rex.]

[ERYSIPELAS. The application of the nitrate of silver as a substance, or in the form of a lotion, so as to blacken the part, appears to have considerable power as a means of checking the peristaltic action of the vessels in which erysipelas inflammation depends. It results upon the effusion of serosity in the cellular tissue, and if applied beyond the erysipelas, will have an ob-

stable to its spreading in any particular direction. By forming a black line with it, the inflammation may thus be kept from running up the neck to the face and head. The use of nitrate of silver in erysipelas has been particularly insisted upon by Mr. Higginbottom. (*On the Use of Nitrate of Silver*.) In the early stages of erysipelas I have often employed it with advantage in the North London Hospital; but it should not be continued too long; for when it fails to lessen the distension of the cellular tissue with serosity, the fluid should be discharged by puncture or incision. Mr. Higginbottom directs the part to be first washed with soap and water, and then dried. The inflamed and surrounding skin is then to be moistened, and the nitrate of silver passed over it once, twice, or thrice; and more frequently, if rapid venification be required. The part is then to be exposed to the air and kept cool.

Of the good effect of mercurial ointment as an application to erysipelas, I cannot speak from experience. Dr. McDowell has tried tartrated mercuric, and makes a favourable report of it. In Mercer's Hospital, it was found also to have considerable power in checking the disease. Two, three, or four applications usually sufficed, with other means. In most instances, the patients were cured. (*See Dublin Lect. of Med. Science*, p. 6.—C.)

(EXCISION OF BONES. Dr. Thomas Harris, of Philadelphia, has excised the elbow-joint for cancer for the first time in America, and with entire success. Dr. Warren, of Boston, has recently repeated this operation with the like result. Dr. Mayer, of Philadelphia, has successfully performed a similar operation, by excising the lower extremity of the humerus and the upper extremity of the ulna for cancer. He professes the incisions of White in all such cases.

Dr. Pincoast, of Philadelphia, has had extensive experience in the excision of bones. He has lately removed the elbow-joint six times, following the plan of Moreau and Syme; and he has excised the upper radio-carpal joint, removing all the articular faces of the three bones, employing Barrow's saw and Liston's forceps. He has also cut out the metacarpophalangeal joint of the great toe for cancer. In all these operations he has had complete success.

In the eighth volume of the North Am. Med. and Surg. Journal, Dr. Allan Giddens relates a case in which he removed portions of three dorsal vertebrae for the relief of paralysis from fracture, and with partial success. The young man had been thrown from a horse, and he was almost universally paralyzed from the moment of the accident. At first the case was regarded as one of dislocation of the vertebra; but Dr. Dudley discovered a fracture after in-

king an incision down to the bone, the base of the spinous process being driven in upon the spinal marrow. The operation was performed by Dr. Giddens for the purpose of removing the pressure from the root, and he excised a part of the spinous processes of two vertebrae, half of the third, and the whole of the fourth of the dorsal vertebrae. The sensation partially returned, and for a time very great hopes were entertained, but ultimately the patient died, life having been protracted, however, for several months, and great relief meanwhile having been afforded to the paralysis. Had not the operation been so long delayed, there is good reason to believe it would have completely succeeded.

Dr. Norris, of Philadelphia, excised the astragalus in a case of simple luxation of this bone, and has published critical remarks upon the practice in the *Amer. Jour.*, vol. xx., No. 49. In the article on Dislocation in this Dictionary, it will be seen that Dupuytren performed this operation in 1828; but numerous cases are on record which were cured by reduction, and others in which no permanent lameness resulted, even when it was found to be irreducible. The necessity for the excision in any case must be rare, but, indeed, such examples of luxation will be found but very seldom.—Russet.]

(EYE. Dr. J. C. Warren first described a case of accidental dislocation of the crystalline lens in the *New-England Med. Jour.* for 1811; and he also, in the same journal, called the attention of the profession to a rheumatic inflammation of the eye, now universally recognised, but until then very little was known of its diagnosis.

Professor Dugès, of Georgia, relates a number of morbid conditions of the eye, in which it became necessary to destroy the organ. This he effected by passing a tomaculum through the cornea, and opening it with the straight bistoury, without touching the sclerotics. There can be little doubt that the removal of the cornea in this way should be preferred to the excision of the eyeball, which in many cases has been unsuccessfully resorted to. Dr. Dugès seems to have used suitable dissection in his cases; and the eye, being lost, the deformity resulting from his operation was greatly diminished, while the removal of the cornea by his method is attended with no danger. No untoward symptoms followed in any of his cases.

Dr. W. A. McDowell, of Louisville, Kentucky, has published in the *Western Journal* a paper on the eye, containing surgical and pathological observations of great practical value. I regret that my limits will permit me only to make this reference to an article which possesses both novelty and merit.—Russet.]

F.

(FINGERS, FREQUENT CONTRACTION OF.

Baron Dupuytren has made some interesting observations on this affection, in which each of the fingers, but especially the ring-finger, is affected. Most of the individuals who have this infirmity have been accustomed to make efforts with the palm of the hand, and to handle bodies of great hardness. When a tendency to the complaint begins, some difficulty is experienced in extending

the fingers, and the ring-finger soon becomes contracted; the carpal phalanx being first implicated, and the others afterward inclining in the same direction. In this stage, the flexion of the two adjacent fingers becomes much checked, but no lameness is yet perceptible in front of, and around the root on the palmar side of the ring-finger. Its second and third phalanges are straight and movable; the first is bent more or less to a right angle, and is movable on the metacarpal

tenes; but it cannot be put into the straight position by the most violent efforts. Dupuytren refers to a case in which a trial was made to cure the paresthesia by means of the application of different weights, which were increased up to 120 pounds without the flexion being removed.

When the ring-finger has become very much bent, the skin is thrown into folds, the convexity of which is towards the fingers, and the convexity towards the radio-carpal articulation. On first inspection, one might suppose the skin to be diseased; but this is not the case. A tense cord is felt on the palmar side of the finger; it extends towards the first phalanx, and may be traced to the upper part of the palm. When the finger is bent, it disappears almost entirely. If attempts be made to extend the fingers, the tendon of the palmaris brevis is felt to move, and the tension is propagated to the upper part of the palmar aponeurosis. The patient is unable to grasp large bodies; and if he try to take hold of them more forcibly, or an endeavor is made to extend the fingers, he experiences severe pain. The course of this disease were formerly referred either to thickening and contraction of the skin, or to the muscles, disease of the flexor tendons or that of the fibrous sheaths, or some change in the articular surfaces and lateral ligaments. All was uncertainty, when Dupuytren had an opportunity of dissecting a hand in which this anomaly existed. A drawing having been first made of it, the incisions were removed from the palm and palmar aspect of the finger, after which the folds and wrinkles had entirely disappeared. From this it was clear that the disorder did not depend upon the state of the skin. As soon as the palmar fascia had been exposed, it was found to be thickened, contracted, and shortened, and that from its inferior part roots or bands proceeded to the sides of the affected finger. On an attempt being made to straighten the finger, M. Dupuytren observed that the fascia became tense. He then divided the prolongations of it extending to the sides of the finger. The contraction ceased immediately, and the finger assumed a very slightly bent position. In fact, the disease was ascertained to be owing to the extreme tension of the palmar fascia, brought on by a contraction of the palm; or the long continued pressure of hard substances upon it. The plan of cure adopted by M. Dupuytren consisted in making a transverse incision, about ten lines in length, over the radio-carpal-phalangean joint of the ring-finger. The skin was first divided, and then the palmar fascia. As soon as this had been done, the finger became straight, and could be extended almost as readily as in the natural state. After the operation, the hand was fixed with a bandage upon a piece of pasteboard for a few weeks, and the fingers kept extended. In one case M. Dupuytren made semicircular incisions—one at the base of the ring-finger, in order to divide the two digital and lateral prolongations of the palmar fascia with this finger; the other as high and a quarter from the first, in the palm of the hand, for the purpose of dividing the digital prolongation at the root, and thus detaching it from the palmar fascia. (See Dupuytren, *Chin. Clin.*, t. i., art. 1.)

In a lecture delivered subsequently to the preceding observations, M. Dupuytren adverts to diseases of the fingers arising from other causes; as a previous wound of the palm known by the name of *ulceration in the foundation of the phalanges* by himself, and characterized with the kind of cord observed when the palmar fascia is implicated,

and a division of the extreme tendons with a cutting instrument, which parts, not being united again, leave the flexors without any antagonists. A contracted wound, producing sloughing of the skin of the palm, may have the same result, if its edges be suffered to be drawn together, instead of cicatrization being completed by the formation of a new cutaneous texture. (See *Chin. Clin.*, t. i., p. 261.) Bands of the palm are frequently followed by this deformity when the pressure in dissection is neglected. Among other causes of permanent flexion, M. Dupuytren notices deformity of the articular surfaces of the phalanges, produced by the long-continued position of the fingers in certain employments, as in bookbinding, tailors, &c.; by wounds of the flexor tendons, at their displacement, in consequence of having been extensively laid open for the cure of whitlow. The wound of a joint may be another cause of contraction of the finger; and a spasm of the flexor muscles may lead to the same consequence. M. Dupuytren's observations on this subject seem to me equally original and valuable. The toes are also liable to a contraction, dependent upon a strain of the plantar fascia corresponding to that of the palm.

I have introduced the opinion of Dupuytren on the origin of such contractures, viz. that the bands hindering the extension of the finger were produced by a permanent contraction of portions of the palmar fascia. The same views are adopted by the late Mr. Henry Cline, and as would appear from an extract taken from his lectures, and published in one of the volumes of the *Lancet Medical Gazette*, even prior to the period when Dupuytren taught the contracting nature of the fascia. The latter had also anticipated the latter as the practice naturally dictated by such contemplation of the cause of the deformity. Mr. Goyrand and Velpeau, however, dissent to the explanation of the subject given by Dupuytren, because the digital slips of the palmar fascia originate in, and are fixed to the base and sides of the root of each finger, while the diseased band is situated in the middle of the finger, and is often prolonged to the third phalanx. They look, therefore, in ascribing this contraction to the transformation of a part of the substance of cellular tissue in front of the phalangeal and fibrous band. M. Sanson also infers that this is the ordinary case, and that the contraction of the palmar fascia is an exception. The treatment recommended by M. Goyrand consists in making a dermiform incision through the skin, over each hand, when extended, to separate the lips of the wound, to detach the fibrous contractile dissection, and to run across these when thus detached from their attachments. (See *Gaz. Méd.*, No. xxxi and xxxv., Aug. 1825.) Sir Ashley Cooper passes a narrow knife under the cord, whether cut through without dividing the skin. —C.]

PISTULA. Thus the presence of a dead piece of bone or of a foreign body often keeps up suppuration, and the fluids effused by the discharge of the matter. When an abscess forms near the anus, the matter becomes, and the fist is determined by the action of the sphincter—a *fistula* is said to be produced. Sometimes a fistula is produced by the continual discharge of some healthy excretion through a wound or wound exemplified in salivary, lachrymal, and urinary ducts. The lining of all fistulae may assume the appearance of certain morbid conditions, though follicles and villi, like those of the

anal canal, have never been observed in it. As Anal sinuses, when most perfectly organized, it can only be compared to the most simple mucous membranes, such as those of the ureters, or lesser branches of the hepatic ducts. The lining of fistula, like mucous membranes in general, when not inflamed, is pale and of a grayish colour; but if affected with acute or chronic inflammation, it exhibits the same shades of crimson and redness seen in a mucous texture. It is also liable to certain affections, which remain placed exclusively to nervous membranes, as fungous growths, callosities, &c. The cellular tissue connected with the lining of fistula may become thickened, indurated, and sometimes give rise to the strabulous cellular tissue in general. Finally, just as adhesions occur take place between the different portions of a surface lined by a mucous membrane, unless a solution of continuity has taken place in it, so the sides of a fistula cannot adhere together, and its cavity is obliterated, unless measures be made to bring the textures and the membrane-like investment of it into contact. (See *Anal. Proct. Lib. Philad.* t. i, p. 261.)—(C.)

Dr. Hayward, of Boston, has performed an operation for vesico-vaginal fistula, which, from its originality and success, is worthy of attention, as well as from its being the first instance in which this disgusting malady has been cured in this country. It may be found described in the *Boston Med. and Surg. Journal* for 1839.

Dr. Mutter, of Philadelphia, has a valuable paper on the different operations for fistula in situ, in the thirty-seventh number of the *Amer. Journ. of Med. Science* for 1834.

Dr. J. Ryan Barton has cured a formidable case of salivary fistula by a modification of the same, and making an artificial opening into the mouth from the duct for its passage by a new style.

Dr. Mutter has cured three out of five cases upon which he has operated for vesico-vaginal fistula. The operation he proposes will be described in his forthcoming work on Surgery, to which I am obliged to refer.

Dr. Paronast, of Philadelphia, has had singular success in treating fistula in perineo consequent upon urethral stricture. In some of his cases there were many fistulous openings, with callous thickening of the subcutaneous layers of the scrotum, perineum, and anus, greatly resembling the anatomy of the parts complicated, in some cases, with enlargement and disorganization of the prostate gland. His plan is to introduce a silver catheter down the stricture, open the edges of the perineum near to the anterior margin of the phrethrum ure, and from this point make a transverse incision running a little obliquely backward, of an inch or more in extent, towards the tubercle of the urethra. He then readily reaches the membranous part of the urethra. In the incision he has never found it necessary to apply a ligature to a large vessel. He then cuts through the stricture at the end of the catheter into the membranous part of the urethra on the plan of Mr. Shaw. He now directs the patient to urinate, and thus discovers the passage to the bladder through the wound, and introduces along the membranous portion of the urethra a silver-pointed silver director, made large for the purpose, along which he carries the end of the silver catheter till it reaches the bladder. The soft parts are then brought over it by suture, and in most cases he is able to effect union by the first intention. Dr. Paronast does not

remove the catheter for six or seven days, when he easily and safely re-introduces another. He has tried Mr. C. Bell's plan, by pushing in a bougie to first in the prostate, and cutting downwards, forward, and outwards, but as there is not retention of urine sufficient to keep the membranous portion of the urethra dilated, this method does not answer.

In the twenty-sixth volume of the *Boston Med. and Surg. Journal*, Dr. E. H. Daxon, of New-York, reports an interesting case of fistula in perineo and vaginal anus consisting in the same individual, and resulting from an abscess in the prostate gland.

Dr. J. Ryan Barton has published in the *Amer. Journ.* for 1840 the particulars of a successful operation he performed for the cure of a vesico-vaginal fistula, which is creditable to his skill and talents.

Professor Parker, of New-York, in operating for stricture lachrymalis, has introduced an improvement, by employing a transverse-bladed knife for the incision, upon the side of which is a groove, so that it continues in itself the advantage both of the knife and director. The incision being made with this knife in the usual manner, it is easy to pass the style along the groove while the knife remains and thus complete the operation with greater facility than by the ordinary method. The same surgeon has also constructed a bistoury with a similar groove on its side as a director, along which a probe may be passed, and which is well adapted for exploring pyramids, as in chronic fistulas, and in searching for foreign bodies.

FISTULA IN ANO.

In the notice of the operation for this disease, Mr. Cooper makes no mention of Dr. Physick's sheathed bistoury, or the instrument of Critchshank, but still directs the use of the director and probe-pointed bistoury. Now, where there is no opening between the gut and sinus, as in incomplete fistula, it is necessary to make one, and the probe-pointed instrument will not answer in these cases. Dr. Physick's sharp-pointed bistoury, with a silver sheath covering both its point and cutting edge, can be introduced in the sinus or the gut until it reaches the point at which the one is to be opened into the other, and then by removing the sheath, the puncture and incision are both easy. Mr. Critchshank's bistoury has a movable spout, which can be protruded or retracted at pleasure, and infuses the want of retention as the instrument of Dr. Physick, by combining in itself both the sharp and the probe points. The latter is preferable, however, because its sheath conceals the cutting edge, and prevents any wound during its introduction.

For the operation for fistula in situ by the linear, in the cases in which this is preferred, Dr. Gibson has constructed an instrument which possesses many advantages, and may be found described in his late work.

Dr. Keil, of Georgia, has had uniform success in curing this disease by incision, he only divides the wound once to prevent adhesion, and afterward relies upon suture and the daily eversion of the perianth.—(Bacon.)

[FRACTURES.—Dr. J. Ryan Barton, of Philadelphia, has introduced into the Pennsylvania Hospital the instrument of compound instrument of an leg by amputation, which has been ever since adopted in that institution with the most satisfactory results. It is described in the *Amer.*

Journal, new series, vol. 1, p. 327, and also in Dr. Norris's edition of *Labor*. The limb is fixed in a fracture-box on a bed of dry straw, and simply surrounded and enveloped in the same material. This dressing is soft and grateful to the patient, keeps up equable and sufficient pressure, while the brain expands when unobscured by hemorrhage, and the pressure is thus attenuated. It may be removed and changed by a splint or syringe, and again applied as often as it may be called for, and without disturbing the limb or reflecting pain. In hot weather, this dressing of clean straw is preferred by Dr. Norris as possessing great advantages by absorbing the perspiration and hemorrhages, and preventing the fever which is apt to attend such cases, and taint the ward of the hospital.

Dr. W. H. Van Buren has a paper in the *Amer. Journal* for 1840, on the immovable apparatus, and its therapeutic application to fractures, and various other surgical diseases, which possesses great merit.

Dr. Mort has treated a number of cases in which fracture of the cervix femoris had occurred, and has uniformly found that, in early and mobile life, union may be expected, even when the fracture is within the capsular ligament. In aged persons, he has never known the bone to unite after such an injury.

In fractures of the femur, he prefers the double-splinted plane in all cases, even when the cervix is broken, and he recommends this plan after trying Pott's, Desault's, Pirovich's, and Jolyer's methods as repeated examples. He finds that the best union can be made by the fixed position, and it is most comfortable to the patient.

Dr. Mort has been very successful in the treatment of ununited fractures by the introduction of a seton, and has three times employed it in the thigh with complete success. He takes this course whenever time, fire, and irritating the ends of the bones by walking in splints do not effect consolidation.

In one case of ununited humerus, when the fracture-ends were at a little distance from each other, and when the seton had been worn for six months without benefit, he succeeded, by caustics. In other cases, after failing to succeed by excision in ununited fractures of the arm, he has subsequently cured the patient by the seton, and in the humerus has found this remedy almost uniformly successful.

In three cases in which the fractured tibia had failed to unite, he has effected a cure by the seton, and one of these was of more than twelve months' standing. In another example, after complete union had been effected by the seton, the patient fell and fractured the bone at the same point. On subjecting him to the ordinary confinement, the cure was as early obtained as though it had been a primary fracture.

Dr. Mort directs that the seton, in these cases should be passed directly between the ends of the bones; for if it merely pass beside the fractured ends, even though in contact, it will not succeed; and hence, when the bones are closely united by ligament or other tissue, a passage must be bored or filed through, to admit the passage of the seton. In general, the time for continuing the seton will be from one to two months, though occasionally a longer time is required. So soon as union has commenced, which is known by the firmness acquired by the limb, Dr. Mort continues the withdrawal of the seton by removing it about every two or three days,

and by the time all are thus removed, the cure is found to be complete.

Professor Parke, of New-York, has treated successfully a case of fracture of the cervix femoris within the capsular ligament. He employed long splints. It was in a female at 60, who had enjoyed excellent health. The limb was but little swelled, and the motion in the joint but slightly impaired. The patient having recovered, the femur has been observed, and exhibits complete osseous union within the capsule. The bone and its fellow are presented in the museum of the College of Physicians and Surgeons, New-York. I have witnessed two cases of a similar result, in which the seat of the fracture was entirely within the capsular ligament; and though both patients are still living, the evidence of osseous union are conclusive. Neither of them was so far advanced in life as Dr. Parke's case, one of them being 40, and the other 52 years of age.

Dr. J. C. Warren has treated 20 fractures of the cervix femoris by the fixed position, and he reports 20 cases of success, a promise he fulfills general experience, and argues well for his method, whether these fractures were within or without the capsular ligament.

For twenty years he reports having treated fractured thighs with great success, employing extension and counter-extension by means of Desault's apparatus improved.

Dr. Isaac Parish, of Philadelphia, has cured a case of ununited fracture of the end of the tibia. (*See Amer. Journal for August, 1831.*)

Dr. Ewe, of Georgia, has used the immovable apparatus of Barton and Velpeux in more than 20 cases of fracture and sprains of the wrist and ankle, with the most gratifying results. He fixes the distal end, after having tried band and starch often enough to judge of their comparative merits.

Dr. J. Ross Barton has met with fractures of the os calcis, in which the fragment is much the length Achilles was stretched and finally drawn up by the contraction of the gastrocnemii. The foot being extended permanently by bandages, an osseous union of the fragments has been obtained in three cases, and though the osseous fragment is prominent, and the tendon shortened to correspond, the patients have recovered without detriment to the motions of the foot.

Dr. George W. Norris, of Philadelphia, reports a case of ununited fracture of the humerus of four years standing, cured by the application of caustic potash, in the *Amer. Journal*, vol. xxii, p. 288. The same surgeon has published a valuable paper on the occurrence of non-union after fractures, its causes and treatment. It may be found in the same journal, vol. vi, No. 5, new series, 1842.

Dr. Nathan R. Smith, of Baltimore, has invented an instrument for fractures of the thigh and leg, which is found by experience to possess extraordinary advantages, especially in the management of bad cases. It is portable, and adapted to the straight or flexed position of the limb, effecting extension and counter-extension to any desirable extent, and he has availed himself of the advantages derived from extending the limb since 1827, and for which his *apparatus* is acknowledged. I regret that my limits will not allow me full detail of the points of merit which Dr. Smith's instrument possesses, but which demands under it expense to any and every other, and that, when

ever it is known, this apparatus is preferred to any other.

Dr. George Fox, of Philadelphia, introduced into the Pennsylvania Hospital, in the year 1828, an apparatus for fractured clavicle, which is described minutely in Dr. Norris's edition of *Lancet's Practical Surgery*, and which is every way preferable to Desault's. Indeed, to this latter there are many and forcible objections, by reason of which it is but rarely applied in America.

Dr. J. S. Heard, of New-York, has published in the *New-York Med. and Surg. Journ.* for October, 1830, a report of cases of untreated fracture treated at the New-York Hospital. In this report, the practice introduced by Dr. J. Keeney Rodgers, of New-York, is illustrated by a number of cases all of which were completely successful.

Dr. Rodgers was led to adopt this course by having a case under his care which had resisted several modes of treatment, including two trials of the seton. Having restored the ends of the bone by extension, he found that the fragments were separated from each other an inch and a half, and it appeared impossible to bring the ends into contact. He then drilled a hole into the medullary cavity through the shell of each end, and passed a silver wire through these holes; and, having then engaged the fragments, the ends of the wire were drawn through a canula which remained in the wound. He thus secured firm osseous union, and Doctors Mist and Cheever have since then repeated this method of treating bad cases with entire success. Mr. Liston and other surgeons, some of them in our own country, have condemned this practice; but as the only cases in which it has been tried have been unfavorable examples, and to which none of the other methods were adapted, some of them having been tested in vain, and as every case has succeeded, the merit of the operation is unquestionable. It is a modification of Mr. White's operation, and will succeed when this fails.—[Russe.]

[FRAGILITAS OSSIUM. For the following cases, detailed at length, reference may be had to Dr. Gibson's late work.

The boy spoken of by Mr. Cooper, in the Dic-

tionary, was a patient of Dr. Gibson, after having twenty-four fractures of different bones, has since deceased, by reason of a partial dislocation of the first and second vertebrae of the neck, after an illness of fourteen weeks.

Dr. Metzger, of Virginia, reports the case of a citizen of Petersburg, Virginia, whose tenderness of the bones was so great that he frequently fractured the humeri, radius, ulna, and clavicles in giving blows, he being habitually pugnacious. Dr. Metzger states that the lady, Frank, and her mother have been broken in his case several times from a sudden twist of the body, and from efforts to save himself from falls. His thick bones have been broken when attempting to get on horseback, and his ribs have been fractured from equally slight causes. He often said that he believed he could break the bones of the forearm by pressing them between the thumb and forefinger. So frequent were these accidents, that his domestics became expert bone-setters, and frequently managed his fractures. His recoveries were very rapid, amputation being readily effected, and very seldom was it necessary to confine him longer than three weeks after either of his fractures.

Dr. Nikison reports a case in which muscular action was of itself sufficient to fracture the bones, those of both arms above the elbow having been broken during a fit. Dr. Herdy, who attended the same patient, testifies that his bones were frequently broken by slight exertion, and in all cases they speedily reunited.

Dr. Goodard has a patient whose bones have been broken fourteen times, though now only twenty years old, and had fractured his thigh three times before he was four years of age, by falling from a step six inches high. The tenderness of the bones was a family complaint in this instance, for his mother had her thigh-bones broken six times; while her brother, at thirteen years old, had suffered nine fractures of the thigh, and two of the arm, besides having one of his hip-joints dislocated. These persons are short of stature, and have small bones, but in other respects have good health.—[Russe.]

G.

[GANGLION. Dr. Eyn, of Georgia, has had extensive experience in the treatment of these tumors, and after trying incision, extirpation, and puncture, prefers the method of acupuncture, as recommended by Velpeau, and afterward relying on pressure for their radical removal. The use of the needles is found to give very little pain.—[Russe.]

[GANGRENOPSIS. In the *American Medical Recorder* for July, 1827, Dr. Jackson, of Northumberland, has published a paper describing a number of cases, with remarks on a disease of children, which he proposes to call gangrenopsis; and in the *Amer. Journ. of the Med. and Phys. Sciences*, vol. v., Dr. Witber has furnished a detail of several interesting cases of this gangrenous erosion of the cheek. Dr. W. has had the opportunity of witnessing five instances in the course of two or three years; three of the middle kind, and one of the most severe form, growing to the power of Burns. Case 4 being the most minutely described, I shall here insert

it, as a suitable appendix to my article on cancer of the jaws of children. "This case occurred in September, 1825, in a little girl 10 years old. It entered upon typhus, in which diarrhoea had been a troublesome symptom. About the fourteenth day, when the fever was apparently beginning to abate, she complained of a feeling of soreness and pain in the left cheek, not far from the angle of the mouth. The part was slightly swollen, somewhat hard, and reddish, like the commencement of a boil. Vesicles impregnated with benzoate was applied, and the soreness disappeared, though the swelling continued, being, however, less hard and rather more diffuse. A day or two after aphthae appeared in the mouth and fauces, for which a gargle of diluted nitric acid was employed. She complained, however, of the cheek being hotter and worse, and the swelling had evidently increased. On the inside of the cheek it protruded in a ridge between the teeth. Lead-water was used externally as a constant application, in addition to the occasional use of the

liniment above mentioned, and the inside of the mouth was frequently washed with honey, medicated with tannic acid; small quantities of wine were given, and one fourth of a grain of sulphate of quinine three a day; also small doses of Dover's powder to regulate the bowels, still rather too loose, and to procure sufficient rest. The cheek, nevertheless, continued to swell, and the mouth became very foul. The aphthæ disappeared in a day or two; but upon the most prominent part of the internal swelling of the cheek was a kind of fatty protuberance or blister, seemingly beneath the whole thickness of the internal integument, which over the swelling was opaque, and of a dirty white colour. This broke the same evening, discharging a small quantity of red fluid, and leaving a sloughing appearance of its membranous covering. It was repeatedly touched during the night and the following day with a strong preparation of mercuric and red honey, sufficiently strong to corrode the sloughing membrane, and make it settle down below the level of the surrounding parts. This, it was hoped, would put a check to the diseased action, and cause the slough to separate. Notwithstanding, it continued to increase during the subsequent night, and on the next morning had nearly reached the angle of the mouth, which looked dusky, and approached to a state of gangrene.

An eminent practitioner from a distance met me in consultation this morning, and advised cauterizing the protrusion with charcoal over the cheek, a small blister externally over the angle of the mouth, and one on the inside of the cheek, of a size sufficient to cover the slough and the surrounding solid edges, while the internal swellings were continued to increase down. The disease, however, proceeded with relaxed rapidity. Gangrene in undisturbed thickness passed in a few hours across the external blister, and at the same time came through the cheek, opposite to the point on the inside first attacked. In spite of the assiduous application of the poultices, these spots spread so as to enclose in the course of the night, and by the next morning involved most of the protruded portion of the cheek. The case was now deemed hopeless, and dissolution was soon expected. The fever being excessive, with a view to lessen it the part was covered with a cloth wet with a solution of the chloroform line (bleaching powder). This lessened the rapid spreading of the gangrene so much, that for hours it seemed almost entirely stationary, but did not become wholly so, though it progressed very slowly till it had covered the whole of the swelling existing at the commencement, reaching almost to the lower eyelid, over the membranous part of the nose of the same side, the upper two thirds of the lip, and half of the chin, including all the cheek down to below the under edge of the lower jaw, and backward nearly to the ear. The parts were completely sphacelated, and had nearly separated; when, at the expiration of twelve days from the first appearance of danger, the little patient died. All the peculiar symptoms of the fever had gradually subsided long before her death.

I have had several opportunities of examining this dreadful disease, but in all the cases I saw, it could be traced to the injudicious use of mercury. In two of them the whole cheek sloughed off, leaving the alveolar bones and the internal structure of the throat exposed, before they terminated fatally.—BRACK.]

[GUMS, INFLAMMATION AND ABSCESS OF.] *Gummat Period.* Inflammation of the gums mostly arises from the irritation of carious teeth, but sometimes from excess of a part of the alveolar process, or from the splintering of it occasioned by the extraction of a bad tooth. Sometimes it originates from exposure to cold, and in other instances from mechanical irritation. When the inflammation, arising from the irritation of a decayed tooth, cold, and some other causes, proceeds to suppuration, the case is then an abscess, here termed a *gummat*. The treatment consists in making an early incision for the discharge of the matter, and, after the subsidence of the inflammation, in extracting any bad teeth concerned in keeping up irritation. The abscess is to be frequently cleaned with an antiseptic gargle. If a fistula form in the gums, it is to be freely divided, and touched with the nitrate of silver, care being taken, however, before reaching to this measure, to remove any carious teeth splinter, or dead portion of bone, which latter proceedings will generally suppress all tendency for forming open the fistula.—C.]

[GUMS, TUMOURS OF.] A very common disease is a thickening of the gums at some particular point, which grows on the form of an excrescence, and generally assumes a hard, bony nature. Some of these swellings are connected with the penetrating of bone, and are disposed to acquire a malignant character; frequently, after they have attained a certain age, the neighbouring part of the bone becomes altered and softened. Other tumours of the gums are merely excrescences from the fibrovascular texture of these parts, not penetrating deeply, not connected with the bone, periosteum, nor sockets of the teeth, and not malignant. The excrescence of the gum, facial, venous glands, is of very different character in size and cases; but, in many instances of the gums, apparently trivial at first, become fatal diseases in the end, if neglected in their beginning, the rule in surgery is to attempt their eradication before they have made considerable progress.

On this subject Sir Charles Bell has made some interesting remarks. "We see (says he) a small tumour of the gums, stationary for a long time, and claiming no attention, at last having its way into the bones of the face, filling up the cells and the cavities of the nose, pressing out the eyes, and rising at last upon the base of the brain itself," so as to destroy the patient. The worst diseases of the gums, according to Sir C. Bell, do not come from the irritation of a bad tooth. "We see a carious tooth attended with alveolitis and purulent, and abscess in the jaw, with singular tumours of the gums; even with necrosis of the jaw." We find the inflammation from the same source amounting to necrosis of parts to that of osteodermatitis. But these are of no account compared to danger with the tumour of which I am treating. This more dangerous disease begins when the shifting teeth are apparently solid, and when we cannot trace it to any common source of irritation. This tumour first appears itself in a small, hard protuberance of the gum, shooting out between two of the teeth; and the teeth being good is an unfavourable circumstance; for when they have become loose are unobscured without betray themselves through a sinus that the cavity is deep, and not as is removed by pulling out the tooth. It does not be curious and originally in fact we have a reasonable expectation of arresting the progress of the

ease by restoring the tooth; but when, independent of the tooth, the tumour has its origin in the membrane of the finger or in the socket, we cannot hope to extirpate the disease without removing the whole system of parts; the tooth, the gum, and the adjacent portion of the jaw. (See *Sir Charles Bell's Surgical Obs.* p. 43, non. Lond. 1816.) A perpendicular dissection of the alveolar process is to be made at a prudent distance from each side of the finger, and to the requisite depth, with a fine saw, any teeth in the way of its action being previously extracted. Then, with a strong pair of forceps, the pedicle of bone between the two fissures is to be broken off. The bleeding, which is copious, may sometimes be stopped by compression (dipped in the tincture of unslaked lime, but frequently requires firm and long-continued pressure with the hands of a succession of assistants, or even the actual cautery).

The soft and more superficial kinds of epulis may be extirpated with a scalpel, considering care to let the incision be sufficiently free and deep,

and then to scrape the alveolar process. He rubs the bottom of the wound with infusio of silver, which will generally stop the hæmorrhage, and lessen the chance of a return of the extraneousness. When the disease recurs often, as it did six times in a case mentioned by John Hunter, the removal of the parts must either have been imperfect, or the tumour cancerous, as happened in two examples which fell under his observation. (See *J. Hunter on Natural Hist. &c. of the Human Teeth* p. 186—C.)

GUNSHOT WOUNDS. Dr. Paul F. Eve, of Georgia, has kindly furnished me the particulars of a case of gunshot wound, in which one ball made six wounds. It occurred in a so-called "affair of honour," in which the balls passed through both thighs, and the right leg having been thrown forward at the moment of receiving the ball, it passed between the scrotum and perineum, inflicting a wound upon both. This ball thus made two wounds in each thigh, one in the perineum, and one in the perineum. The patient eventually recovered, and is now well.—RICH.

H.

HEMATOCELE. (From *hæm*, blood, and *cele*, tumour.) A swelling of the scrotum, proceeding from, or composed of, blood.

The term has sometimes been applied to every kind of extrusion of blood about the scrotum and spermatic cord, but at the present day it is usually restricted by British surgeons to a collection of blood in the cavity of the tunica vaginalis. Extrusion of blood in the cellular tissue of the scrotum and spermatic cord, or within the structure of the testicle itself, form, however, arrangements with hæmatocele. The law swelling is generally pyrexia, like hydrocele, but is distinguished from it by its greater weight and firmness, its want of transparency, its obscure fluctuation, and its cause, which is usually a blow upon the scrotum, or an accidental pressure of some vessels of the testicle or tunica vaginalis leading a hydrocele. When the latter membrane has been lacerated or much distended by the serous fluid of hydrocele, it becomes thickened, and its vessels, especially those of its inner surface, enlarged, and even varicose. If one of these becomes the way of the instrument with which the hydrocele is tapped, it is of course wounded, and then the fluid which is discharged is deeply tinged with blood. Should the bleeding continue after the evacuation of the hydrocele, the blood will accumulate in the cavity of the tunica vaginalis, and in the course of two or three hours the scrotum will again be considerably swollen. In one or two examples, I have known hæmatocele follow the tapping of a hydrocele with a lancet or other sharp-edged instrument. Sir Astley Cooper has noticed this risk as attending the plan of tapping a hydrocele with a lancet. (*On the Structure and Use of the Testis*, p. 212.) A gentleman in the Fleet prison told me his head to tip his hydrocele with a kind of long spring-lance of his own invention: the operation was followed by the rapid formation of a very large hæmatocele.

Sometimes one of the enlarged veins of the tunica vaginalis bursts of itself, after the fluid of a hydrocele has been discharged, and hæmatocele then comes on, as it were, spontaneously. According to Sir Benjamin Brodie, hæmatocele may arise from a diseased condition of the arteries. "This is analogous to that which occurs in the brain under the form of sanguineous apoplexy. There is a natural change which takes place in the arteries of old persons; they become ossified in patches and dissects; and I have known this to lay the foundation of hæmatocele." (*See London Med. Gaz.* vol. 1831-32, p. 937.)

As Sir Astley Cooper observes, hæmatocele is often connected with hydrocele, and is a consequence of it. The latter disease frequently becomes complicated with hydrocele from an accidental blow on the tumour, occasionally a rent in the tunica vaginalis. In such cases, operated upon by Sir Astley Cooper, this instrument had been ruptured to the extent of between one and two inches. The same distinguished surgeon records the case of a gentleman, in whom hæmatocele arose, not from a blow, but from excessive bodily exertion. (*On the Structure, &c. of the Testis*, p. 213-215.)

However, of all the causes of hæmatocele, a blow on the scrotum is the most frequent, and especially a blow from the point of the saddle in riding. I have known the disease produced, however, by external violence of different kinds; as by a fall against a piece of timber, by which the scrotum was violently struck. After such accidents, the scrotum will suddenly swell to double or triple its natural size. Every swelling so produced in the scrotum by effused blood is not invariably a collection of this fluid in the tunica vaginalis, for sometimes the extravasation is in the loose cellular tissue external to this membrane. Hæmatocele, as to be distinguished from the latter case partly by the density or firmness of the tumour, its slow or fluctuating nature, and by presenting itself more on one side of the scrotum than the other; while an extravasation of blood in the cellular tissue generally is more diffused, produces a dark blue discoloration of the part, and extends more or less to both testis.

When hematocele occurs in combination with hydrocele, the blood is mixed with the serum fluid contained in the tunica vaginalis, and partially dissolved in it: if the quantity of blood be small, the solution is complete; but in the opposite case coagula are formed, which remain undissolved. (See R. Brodie, &c.)

In the dissection of some hematoceles, the tunica vaginalis is found excessively thickened; and the blood in it, whether coagulated or fluid, is of the colour of coffee. Sir Astley Cooper refers to a preparation at St. Thomas's Hospital, exemplifying the serious mistake of removing the testicle, while the true disease was merely hematocele. The tunica vaginalis was excessively thickened, and filled with coagulated blood of a brownish red colour. (Op. cit., p. 215.)

A negro died in St. George's Hospital who had an enlargement of one testicle; but as it had increased little or to no consequence, the surgeon had not been consulted. Sir Benjamin Brodie examined the part after the patient's death, and found a very large quantity of gummy blood in the tunica vaginalis, and at the back part a soft, pulpy mass was seen, not at all resembling the testicle in structure, and only recognisable as such by its connecting with the epididymis and vas deferens. Sir Benjamin Brodie conceives that the changed state of the testicle had been occasioned by the pressure of a large quantity of blood. (See Lond. Med. Gaz., 1831-32, p. 927.)

Hematocele is sometimes unaccompanied by pain: this is the case when the quantity of blood is small, and no inflammation present. Under other circumstances, the disease may be attended with excessive pain, and ending in abscesses, gangrenes, and dangerous degrees of constitutional disturbance. This was exemplified in the person whom I have mentioned as having produced hematocele by plunging a large lancet into his own hydrocele, for the purpose of curing it himself. In this instance, which I viewed with Mr. Beardsley Cooper, if a free and prompt incision had not been made to discharge the matter and purify blood, the patient would soon have lost his life by the violence of the constitutional disturbance. Sir Benjamin Brodie mentions a painter, who was in the habit of drinking to excess, and who, while climbing a ladder, was seized with pain in the testicle; and an enormous hematocele formed. In this patient the symptoms he first were more nearly allied to meningitis than delirium.

If hematocele be occasioned by a laceration, and not accompanied by hydrocele, and the quantity of blood in the tunica vaginalis be moderate, the treatment should consist in keeping the patient in the recumbent position, applying leeches, administering purgative medicines, and covering the tumour with a cold lotion, which will have the effect of checking any further internal bleeding. These means will prevent inflammation, and, after a time, the blood will probably be absorbed. Were the quantity of blood considerable, no pressure might cause an absorption of the testicle (See R. Brodie, &c.), at all events, it would be likely to excite inflammation, and have little or no chance of being absorbed: in such a case, therefore, the best practitioners agree respecting the propriety of laying open the tunica vaginalis and taking out the blood.

If hematocele be combined with hydrocele, and free from much inflammation, Sir Astley Cooper recommends making an incision into the tunica vaginalis, discharging its contents, and,

without displacing any lint into the cavity, leaving the scar to be completed by the process of inflammation. (On the Structure, &c., of the Testis, p. 216.)

If, on drawing off a hydrocele, the contents are mixed with blood, Sir Benjamin Brodie always the fluid is collected again, and repeats the tapping at intervals until no blood is mixed with it. The injection may then be used with success. Should the quantity of blood be large, he regards the expectation of its being removed by absorption as hopeless, and therefore punctures the tunica vaginalis with a lancet, introduces a director into the opening, and then enlarges it with a scalpel. (Id.)

Whoever has read the observations of Pott on this subject will know that the operation of laying open the tunica vaginalis in the case of hematocele is sometimes followed by a severe attack of symptomatic fever, delirium, and even death. In unfavourable conditions, the symptoms will generally prove serious, whatever be the mode adopted in discharging the blood or the internal treatment. But now that the plan of introducing lint and other absorbent substances into the exposed cavity is abandoned, bad cases are far less frequent than formerly. The violence of the symptoms will generally depend upon the degree of inflammation in the parts, and the kind of constitution in which it occurs. If hematocele excite inflammation, the state of blood purifies, and a gangrenous suppurative follicle, attended with an accumulation of extravasated hydrocele in the part, and most urgent danger. Here a free opening must be made without delay, the scrotum polished or covered with cold lotion, and the patient kept under the influence of the muriate or acetate of morphia.

Mr. Pott, in his account of hematocele, comprehends one species, which he describes as an extravasation of blood within the tunica albuginea.

I confess that no good reason appears for including cases of this kind with hematocele; for what are they but diseased testicles which have been punctured, either on account of their containing a fluid, or really having within their cysts filled with chocolate-coloured malar fluid, as I have seen in hundreds of instances of sarcocoe? and, whatever blood is discharged, is not extravasated in the substance of the testis precisely to the purpose, but issues as a necessary consequence of that proceeding.

Another species of hematocele, noticed by Pott, arises from a bursting of a branch of the spermatic vein, between the groin and scrotum within the sheath of the cord. This, which is generally produced by great or sudden exertions of strength, force of agency, &c., may happen to persons in the best health.

I cannot conceive that, in any case, if a mere rupture of one of the spermatic veins, it can ever be justifiable to tie the whole spermatic cord, and then perform castration, though Pott avows this plan, if the bleeding branch cannot be tied early. Dissecting applications and an occasional purge will almost always disperse the swelling; and if not, opening it, and taking out the blood, applying cold, or, if necessary, filling the cavity with lint, and using compression, would be, according to my humble judgment, the most judicious treatment.—C.]

DIABETES. Dr. Isaac Parry reports two cases of congenital double diabetes, with an operation, and remarks on the method of separating

the bridge of the nose in these cases. (See *Amer. Journ. for May, 1834.*)

Dr. Mott, of New-York, has had extensive experience in this operation, having performed it nearly 200 times. In simple cases he recommends that the operation be delayed two or three months. In the compound double hare-lip he operates on both sides at the same time, with one set of stitches, leaving the intermediate portion in the form of a wedge. In the complicated variety, with fissures through the bones, he recommends an early operation, and has performed it successfully in nine days after birth, though he thinks it better to wait two or three months. When performed thus early, the fissure in the bones will close in the course of a single year. Such has been his experience in more than 20 cases of this form. He has also treated compound complicated cases, having a double fissure through the bones, with successful success.

The importance of teaching the child to feed with a spoon before attempting this operation should never be lost sight of, nor should the child be permitted to nurse after the operation until the lip is united. Dr. Mott has never employed pins in any form of this disease, but finds the interrupted suture to be adequate to every variety of hare-lip. I have lately had occasion to operate upon a young lady of 30 years of age, who in infancy had been twice operated for with the twisted suture, and in both instances the pins were torn out, and the deformity being increased, all hope of cure was abandoned, and she grew up, therefore, without its repetition. In this case, which was a compound double hare-lip, though it was necessary to remove as much of the lip as bore the cicatrices of the former operations, I employed only the interrupted suture and strips of adhesive plaster. The result as this whole case has been most gratifying, perfect union having taken place in four days, so that the stitches were removed, and scarcely a mark of the deformity can be discovered.

In the compound complicated variety of hare-lip we often find a projection of one side of the jaw-bone in the form of a proboscis. This should be removed, as preliminary to the operation on the soft parts, by a strong pair of scissors or the bone-saw. Dr. Mott has occasionally found it necessary to employ the actual cautery in these cases, to arrest the hemorrhage from the bone which has followed the removal of this protuberance. In such cases it is better to defer for a few days the incision and suture to the lip. Dr. March, of Albany, has been very successful in removing these shocking deformities by a similar operation. He too employs interrupted sutures, nearly transfixing the lip, and introducing them nearly half an inch from the edges of the surfaces which are expected to unite.—(Roux.)

[HEMORRHAGE.—TOUNIQUET.]

At the present day, the means for the temporary stoppage of the flow of blood through the arteries in operations are reducible to two, viz., pressure, and, in a few instances, the preliminary application of a ligature on the trunk of the vessels exposed to blood in a dangerous degree. Pressure is made either with mechanical instruments or the hand. In prostates, M. Dupuytren rarely employed any other means but the hand of an intelligent assistant, and it was only in special cases that he had recourse to the ligature or mechanical pressure. The same rule is adopted by Mr. Liston in University College

Hospital; and I sometimes dispense with the tourniquet myself. Two conditions are necessary to render pressure effectual, whether made with an instrument or the hand; the superficial situation of the artery, and its position upon a bone, or some other part sufficiently yielding to admit of the vessel being pressed against it. (See *Dupuytren, Clin. Chir., t. iv., p. 371.*)

M. Dupuytren confirms, that every experienced operator is well aware of, namely, the fact of the flow of blood through the larger arteries admitting of being commanded by means of moderate pressure. But this must be made with precision, and particularly to the surface, which serves as a point of resistance. The inclination of the surfaces of the bones on which the vessels lie should therefore be recollected. For example, that of the upper surface of the horizontal branch of the maxilla turns upward and forward, and that of the fast rib upward and slightly outward. Consequently, in the groin, the pressure should be directed from above downward, and from before backward; and in the hollow, above the clavicle, from above downward, and from without inward. If the operation short to be performed is likely to be long, or the artery is large or rather deep, M. Dupuytren recommends the assistant to place the fingers of his unoperated hand over those which compress the vessel, in order to second their action, and hinder them from being fatigued. But, before beginning the operation, the surgeon is always to assure himself of the exactness of the pressure. In some regions of the body, and in thin persons, the diastole and systole of the vessel are perfectly visible, and then the stoppage of them denotes that the pressure is well made. The total interruption of the pulsations, as ascertained by the touch, will leave no doubt on this point. There are some anastomoses in which every moderation of pressure may be dispensed with, even though arteries of great size are concerned; such are cases in which the principal artery will be cut only in the final division of the parts, and in which an assistant who can be relied upon will let his fingers follow closely the knife, and seize hold of the flap containing the artery, and compress this vessel just before the section of the flap is completed. This method is practicable in anastomoses at the shoulder, and even in those of the hip. M. Dupuytren knew of only one case in which the preliminary ligature of the artery was absolutely necessary in amputation, viz., that in which the disorganization of parts, and of the artery in particular, was such that a defective ligature on the surface of the stump would in all probability fail. In this circumstance he cautions tying the arterial trunk above the point at which the amputation is to be performed. (See *Clin. Chir., t. iv., p. 282, 285.*) I would ask, however, should this measure be preliminary, or ought it not rather to be deferred till the failure of the ligature on the face of the stump has been proved? The performance of two series of operations instead of one must never be undertaken without a positive necessity. Most of the preliminary operations on the trunk of arteries, hitherto performed for the prevention of hemorrhage during amputations, and in the removal of the upper or lower jaw, are now considered to have been unnecessary. In England, we should never anticipate in parts known beforehand to be so disorganized that ligatures would have no chance of securing the vessels on the face of the stump.

In the article *Ampu'tation*, many observations will be found on the advantages and disadvantages of tourniquets in that operation. M. Dupuytren sometimes employed, instead of a common tourniquet, what he terms a *compressor*, which makes pressure only on two opposite points of the limb, but, as he acknowledges, it would not be sufficient, if it were necessary, as in a case of extreme bleeding, to arrest the blood in the arteries of the limb. (See *Clin. Cir.*, t. iv., p. 268.) The compressor is an old instrument, consisting of a segment of a circle of steel, and the pressure of which is regulated by a screw. It has often been tried in England for the cure of postural aneurism. It is an instrument which, I think, ought always to be kept ready in hospitals, where many cases present themselves, especially of secondary hemorrhage from stumps, the painful achilles, &c., where its application might be of important use. Professor Requin, of Pisa, in a case of aneurism, where secondary hemorrhage took place from the femoral artery, high up the limb, and when, in consequence of disease, any other ligature would probably have failed, applied Dupuytren's compressor, and thus made moderate pressure on the bleeding point with complete success.

TORSION.

"As even the most considerable arteries, in cases of lacerated wounds, frequently do not bleed, in consequence of the violent contraction of these vessels, and the change produced in the disposition of their tunics, the idea of stopping hemorrhage by methodically twisting the end of the wounded arteries, led to trials of what is called *torsion*. The practice was first hinted at by Galen, and proposed in modern days by M. Amussat, in 1820, and about the same period, also, by MM. Velpeau and Thierry. (See *Saxen, des Hemorrhagies*, p. 155.) After having ascertained, by experiments on animals, that torsion was capable of arresting hemorrhage from the cerebral, tracheal, and caecal, and other arteries of mammals, M. Amussat tried this method on the human subject in angustion, contusion, and the removal of the tongue. In one case he adopted it after amputation of the shoulder-joint. In none of these instances did any secondary hemorrhage arise; but union by the first intention was followed only in one of the cases referred to, viz., that of a child. In 1828, M. Lisler, surgeon to the new hospital at Berlin, tried the plan with equal success; and about the same period it was first resorted to with success by Dr. Frick, of Hamburg, by MM. Rost and Dieffenbach, of Berlin, and by M. Schöndor, at Dresden. On the other hand, in France, the practice of torsion proved unsuccessful after two amputations performed by Professor Delpech. As the patients did not die of secondary hemorrhage, perhaps their cases have nothing to do with the advantages or disadvantages of torsion. In the hospital of St. Louis, at Paris, however, torsion failed as five out of six cases of amputation. Baron Dupuytren, having been requested by the Institute to make a report of the merits of the plan, tried it in the Hôtel Dieu, and came to the conclusion that *torsion may be safely applied to wounds of small caliber, but that it is imprudent to trust to it when there are of a large size*. (See *Clin. Cir.*, t. iv., p. 319.) In a certain number of instances, torsion of the arteries has been followed by extensive inflammation and abscesses in the sheath of the artery.

With regard to its increasing the chance of union by the first, inasmuch as no extensive aneurism is left in the wound, experience has not proved that it has any advantage over the ligature (*Dupuytren*, vol. vi., p. 403), and, as M. Hunter's researches show, the process of torsion kills a small portion of the artery, and the little slough is, in point of fact, cured as much an extraneous substance as the ligature itself. (See *Traité Théorique et Pratique de la Ligature*, &c.; also *Saxen*, Op. cit., p. 161.) Torsion is practised in two modes; *simple*, which is termed by the French *torsion libre*, the end of the artery is taken hold of with a pair of forceps, gently drawn out, and twisted round from left to right eight times, according to its size. This is the plan adopted by M. Thierry (*Art de Tisser des Armes*, Paris, 1820) and by Dr. Frick; but as it has been found sometimes to produce inflammation, extending along the coats of the vessel, and even to rupture a collateral branch, the plan recommended by M. Velpeau is mostly preferred in France. This gentleman takes hold of the end of the artery with a pair of forceps, having a grasper or not, draws it out of the wound, and secures it from the surrounding tissues; then he takes hold of it near its base with a second pair of forceps, with which he fixes it, while with the first pair of forceps he performs the torsion, three or four times for small arteries, and eight for large ones. (See *Le Nouveau Système des Hemorrhagies*, &c., Paris, 1830.) Some improvements were made in the practice of torsion by M. Amussat. He prefers torsion with longish, flat blades, and which when being kept firmly shut with a screw. He was particularly at dividing the inner coats at the base of the end of the artery with his finger-nail, or the second pair of forceps, and then makes them away from the surface of the vessel, as it were, into the vessel. The torsion then only affects the external coat. The artery is then closed by a kind of double valve, on either former side, the formed of the internal coats, and another by the twisted external coat.

In practicing torsion, great care should be taken not to introduce one of the blades of the forceps into the mouth of the artery; for then all the three coats might be torn; and the bleeding not be stopped. (See *Dupuytren*, *Clin. Cir.*, t. iv., p. 315.)

We find, then, that torsion does not consist in methodically twisting the end of the artery, but that the two internal coats are also to be separated, torn, and pushed back from the external by the instrument adopted. Then the torsion is of the external coat.

As the twisted end of the artery sloughs, and necessarily excites some degree of suppuration, this fact seems to explain why torsion is not less objectionable than the ligature, as preventing union by the first intention. On the whole, I believe that M. Dupuytren's report of it, above referred to, is as correct as it is concise. The ligature only interferes with union by the first intention in the part of a wound where it lies; the rest may still heal in the desirable manner.

The hemorrhage from the base of lacerations sometimes proves exceedingly obstinate, and in stages of death from this cause have occasionally happened, particularly in children. When common methods fail, the plan has been recently tried of passing a fine sewing-needle through the skin on one side of the wound, and another through the skin on the opposite side, and then

twisting were thrust round the needles, so as to draw them together, and close the hole. The experiment fully answered. (*See Lond. Med. Repository*, January, 1819, p. 23-26.)

Though arterial hæmorrhage in operations has received full attention, it must be acknowledged, with M. Dupuytren, that venous bleeding has not attracted due consideration. At the instant of the soft parts being divided, when the name of the blood has been suspended by compression, a profuse quantity of the fluid sometimes gushes from the wound. Inexperienced surgeons, alarmed by this circumstance, stop the operation, and, by deranging the compression already made, rather increase than lessen the bleeding. Here, according to Dupuytren, the colour of the blood should guide the operator. If dark-coloured, it comes from the limb below the incision, and, as it will soon cease, it is of no importance. But in operating on parts abounding in veins, and in which the circulation has not been interrupted, the dark-coloured bleeding will sometimes go on, fill the wound, and hinder the operator's proceedings. This is often illustrated in laryngotomy and tracheotomy. In other instances, the blood flows out profusely from the large veins which are divided, the patient turns pale, and seems as if he would perish on the operating table. Dupuytren observes that the continuance of such hæmorrhage depends more upon the patient suspending respiration than on the size of the veins, and the blood not being then able to pass through the lungs, makes its escape from the veins divided in the operation. Here it is essential to apply ligatures; because, if one set of veins were tied, another set would begin to bleed. But correctly the patient has filled his lungs two or three times completely with air by making full inspirations, the hæmorrhage ceases. These precepts were never forgotten by Dupuytren; whenever he divided considerable veins, either in the trunk, face, neck, or any part of the limbs. (*See Leçons Orales de Chirurgie Clair.*, t. IV., p. 285.) It would appear, from the researches of M. Ponsomme, that the interruption of respiration only has influence on the portion of the venous system above the diaphragm. (*See Journ. Chim. Médic. de Médecine*, t. I., p. 286, et t. II., p. 57, *Sic.*, Paris, 1831.) However this may be, the practical observations of M. Dupuytren are highly important with reference to venous hæmorrhage in the extremities of thoracic tumours from the neck, or aneurism tracheotomy, and all other operations in the thoracic region of the neck, a region so abundantly supplied with veins of all sizes. The long and deep inspirations, however, recommended for the suppression of venous bleedings, are suggested by M. Sauton to have had, in some instances, a share in promoting the entrance of air into the veins, particularly when one of those in the upper part of the body has been wounded, and, in consequence of its position being indurated, it gapes, as with such aneurism to M. Delpech, in the axillary vein (*Chir. Chir. de Montpellier*). The passage of air into the wounded veins, observed by Broussais, Dupuytren, Gracé, Mont, and Clerot, usually destroys the patient almost instantly, unless care be taken to place a finger over the wound in the vein, as was done by M. Clerot. (*See Sauton, des Hémorrhagies Traumatiques*, p. 81.)—C.

HEMORRHOIDAL TUMOURS. Dr. J. C. Warren has operated very frequently in this disease, and with extraordinary success. In 100 cases he practised circular excision by the knife,

and in 25 he fastened both the ligature and the knife; not less so, in any of them, met with any bad consequences. A very large proportion of the cases were completely cured, and in all of them the patients were so benefited as not to regret the operation. In seven cases, perhaps not demanded the use of the knife, and in all these he succeeded without any untoward results.

Indeed, the use of the knife for the removal of hæmorrhoidal tumours, as advocated in the Dictionary, is practised in the United States to a great extent. That alarming hæmorrhage has occurred in the limbs of surgeons, requiring the actual cautery for its suppression, will be seen by the testimony of Dupuytren, who nevertheless strenuously advocates the use of the knife.

Very many American surgeons, however, employ the ligature, variously modified, instead of the knife. Some, by passing a needle through the tumour doubly armed, and then tying the ligature on both sides, and allowing the ligature to remain until it sloughs off, which often requires several days. Many others, however, adopt the caudæ and wire ligature, as recommended by Dr. Physick, and Dr. Gibbon has succeeded in this way in cases as formidable as those described by Dupuytren, without any of the mischief which followed the excision practised by that surgeon. Its advantage consists in the wire being at once permanently tightened, so as to destroy the part in a few hours, when it can be removed, instead of waiting the protracted lapse which the ordinary ligature requires for successive days and nights.

Very valuable practical hints on this topic will be found in Dr. Gross's late edition of *Lancet's Elements*.—RACCOL.

HERNIA. In the last volume of the *Transactions of the Medical and Surgical Association*, my friend, Mr. James, of Exeter, has inserted an interesting paper on the signs which distinguish the sac in hernia. Among others, are perhaps admitted to be writers, he mentions the possibility of drawing down more of the intestine. "If (says he) we have opened the sac, I believe I may affirm that it will rarely happen that we cannot draw down some further portion—a very good practice, say, on many accounts; while, if we have not, this will be manifestly impossible."

"Another point, which has not been adverted to, is the very size of the tumour, which offers, as it appears to me, a highly important indication; for if it be small intestine, it must, if exceeding the dimensions of an ordinary knuckle, present the appearance of a convoluted, supposing the sac has been opened, or of great intestine, it must exhibit the characteristic appearance of bands." (P. 151.)

Dr. O'Heime is the author of some original observations on the primary causes of strangulation, and on what he considers to be an improved mode of performing the facts of cases of intestinal hernia. The latter consists, first, in the introduction of a gum-elastic tube into the sigmoid flexure of the colon, and retaining it there while the taxis is used. Secondly, if this fails to diminish the size and dimensions of the hernial tumour, a syringe is attached to the tube, and encephalic mucus thrown up, the water process being repeated until the bowels are sufficiently freed either solid and fluid contents, and then the tube is again introduced without the syringe being attached to it.

Dr. O'Heime informs us that he has employed

this treatment, and seen it employed by others, during the last eight years, with the most gratifying results. Some of the cases alluded to, with an exposition of the principles on which they were treated, appeared in *February, 1833*, in his work, entitled *New Views of the Process of Defecation*, &c., and others were afterwards recorded in the *Lond. Med. and Surg. Journal*. It is Dr. O'Beirne's doctrine, that the abdominal openings are perfectly inactive in the production of strangulation, and that the causes of this state arise in the protruded parts themselves. He argues that, when the protrusion takes place, a current of fluids is impelled into the protruded intestines, "which becomes so distended as to be driven (the sac alone being interposed) against the firm margins of the ring, and often with such force as considerably to dilate the latter. The distension is of course resisted by the ring, and, according to the situation of the hernia, either by a strong or a weak fascia; but below this point, the bowel being opposed by little more than external restraints, yields readily, and becomes rapidly enlarged to a size so disproportionate to that of the opening through which it descended, that it is no longer capable of repassing into the abdomen. There is, at the same time, another cause operating to prevent its return for the great expulsive muscles, although they soon cease to act simultaneously or with the same force, still act so as to direct and maintain a constant current and pressure of fluids against the strangulated gut. There are reasons for believing also, that the bowel is more or less shagled above as well as below the ring, so that the latter lies imbedded in a hollow formed by the sac and the inguinal. In this way, pressure from within and resistance from without unite in causing the margins of the hernial opening, although totally inactive, per se, to produce a much greater degree of constriction of the sac and the intestine than they could possibly produce if they really possessed the activity attributed to them by many." Dr. O'Beirne differs from Mr. Goodenough in believing that, when a knuckle of intestine becomes strangulated, air may still pass into and out of the bowel so connected, as consequence of the existence of a narrow channel of communication between the protruded bowel and that within the abdomen. That this is frequently the case, I think all practical surgeons will admit; but whether it is constantly the case, seems to me questionable. Be this as it may, Dr. O'Beirne contends that the cavity of the strangulated gut is not dilated, but permits air to pass freely into and out of it, that all the portion of the small intestine within the abdomen and the whole of the caecum and colon are distended, and also afford free passage to the air; and that the sacrum is contracted, and alone opposes the escape of this elastic substance. If, previous to a double-strangulation, the bowels should be loaded with solid and fluid feces, so as to prevent the passage of fluids, or the success of the first introduction of the tube, Dr. O'Beirne insists on the necessity of persevering, with the aid of repeated enemata. The gut-tube used by him is sixteen inches in length, and the syringe about seven inches long and one in diameter. The tube should be made soft by immersion in cold water, made straight, and then a few inches of it are to be well oiled. It is to be introduced as the patient lies on his left side, and passed up inch by inch, and in the course of the rectum. If stopped, it may be slightly withdrawn, and afterwards passed gently

upward. But if it cannot be got further up without much force, the syringe is to be attached to it, and fluid thrown up as a strong antispasmodicum by an assistant against the press. is resistance, while the surgeon urges the tube freely upward. Many other interesting observations on this practice have been inserted by Dr. O'Beirne in the *Dublin Journ. of Med. Science*, vol. xiv., art. 7-9-G.

[The late Dr. Joseph Parikh, of Philadelphia, a short time before his death, published a volume of "Practical Observations on Strangulated Hernia, and some of the Diseases of the Urinary Organs." In this work the student of surgery will find a greater amount of practical information on this subject than can anywhere else be obtained in our language. The same surgeon has also published in the *Eclectic Repository*, vol. x., p. 108, a case of strangulated hernia, with observations on the treatment of anastomosing aneurism.]

In the *American Journal* for May, Dr. Evers reports two interesting cases of hernia, in one of which the patient has entirely recovered after the coccyx was removed.

Dr. N. R. Smith, of Baltimore, has operated for strangulated hernia in thirty-two cases, and the result of his operations has been the entire recovery of the patient in thirty-three instances. Dr. Munsey, of Cincinnati, has performed thirty-two of twenty-four operations for strangulated hernia, and generally with successful and permanent results in two of them.

Dr. Parroquet, of Philadelphia, has devised and executed an important operation for the radical cure of reducible hernia: by the insertion of the sac after its contents were returned, and a ring applied over the internal ring, so as to shut off the abdominal cavity. He employed for the purpose a gold-stilet or cannula, stretched upon a large acupuncture needle, the tube being then and closely fitting the needle, so as to enter the sac without difficulty. The needle being well drawn, with a small syringe he injected thirty minims of tincture of iodine in some cases, and the first index in others, into the sac. A compression and strong truss being then applied, the patient was confined to bed for a fortnight. When the sac was small, he found a single operation sufficed to prevent the descent of the hernia, but when it was of large size, the injection was repeated two or three times. Two cases were thus treated at the Philadelphia Hospital, and no permanent inflammation or other untoward result followed. These patients were now relieved from wearing a truss, and he writes afterward, while they remained under observation, had no return of the hernia.

Dr. Detmold, of New York, has lately published the same operation as for strangulated hernia in a case of reducible hernia, and effected a radical cure. He was induced to attempt it at the importunity of a lady, who was distressed by her husband immediately after marriage, on discovering the hernial tumour under which she had long laboured, but of which he had not been informed. He recorded the consternation of the patient on removing him from his marital contract, and she therefore applied to Dr. Detmold and besought him to perform the operation, declaring that, unless this obstacle to her union could be removed, she would drown herself. The nature of the infirmity was fully explained to the husband, but his prejudices resisted every remonstrance. Under these circumstances, Dr. Detmold proceeded with the operation as in cases

of strangulation, and, having cut down upon the sac, he reduced it without opening it, scathed the aneurism and filled it with fat, producing granulation and closure of the sacculus, effecting a complete cure of the hernia. When the recent husband heard of the recovery of his wife, manifested in submitting to this painful and dangerous operation, he consented, and, without waiting for the result, expired, but, as his wife and the parties are ever since happily united, surgery having removed the only hindrance to domestic felicity.

M. Guerin, of Paris, has recently applied the abdominal method to the operation for strangulated hernia. The only case yet reported in the *Gazette Médicale* was a congenital epiphora, which had been strangulated three days. The division of both the abdominal rings, and of the antero-superior wall of the inguinal canal, was effected subcutaneous, and the reduction was immediately accomplished. If this approach continues to prove the success of this method of operating, vision will soon cease to be necessary among the qualifications for a surgeon; for a blind man could perform subcutaneous operations as well as M. Guerin himself, since a knowledge of anatomy with the sense of touch are the only requisites in such operations.

Complicated cases of hernia, in which a finger-like protrusion or duplication of the peritoneum was found covering the sac, so as to prevent the appearance of a hernial sac entering to the true hernia, and rendering diagnosis difficult until, on issuing it in the operation, the parts within were found to be unlike either intestine or omentum, and both to be confined into the abdomen. Professors McDermock and McClan, of Philadelphia, have encountered these cases.

The various assistants proposed for the radical cure of hernia have attracted much attention in the United States within the last ten years, and several controversies of the nature of quackery have been introduced to the public as possessing the power of accomplishing this result with considerable certainty. The alleged radical cure of hernia in the person of a farmer in Kentucky, by the substitution of a rough chip of wood for the pad of his instrument, which had been worn out and could not be immediately replaced, led to the construction of several instruments by Dr. Hood of that state, which were said to prove successful in most cases, by causing obliteration of the neck of the sac and its adhesion to the surrounding parts by adhesive inflammation.

These instruments, which had been introduced by the agents of the inventor to the notice of the French and English surgeons, have not maintained their position in professional confidence after undergoing the test of experience; but in the investigations induced by these publications originated a series of inventions by Dr. Hester Chase, of Philadelphia, which have received the sanction of many of the most prominent surgeons. In the year 1831, the whole subject of the radical cure of hernia by means of trusses was referred by the Philadelphia Medical Society to a special committee of three surgeons, and, after three years' careful observation, they produced a report highly favorable to the claims of the inventions of Dr. Chase. Their opinions and cases will be found in a preliminary report published in the *American Journal of Medical Science* for February, 1836, and a final report in the same journal, for August, 1837. The views of the investigators

fully developed in a work entitled "Treatise on the Radical Cure of Hernia by Instruments, by Hester Chase, M.D., Philadelphia, 1838," which contained, also, an extended analysis of the *modus operandi* of all the variety of the truss.

The claims of the advocates of the Medical Society, Dr. Reynold Coates, considering the theory of cure by agglutination as erroneous, and attributing the unsuccessful results of the instruments of Dr. Hood, and the failure of some of the earlier attempts of Dr. Chase, to the modifications of the form of the pads employed, especially with the view of producing inflation and consequent adhesion, strongly urged the opinion that the occasional success attendant upon the use of ordinary trusses, and the happier results of some of the novel contrivances, were due, not to adhesion, but to a coaction of the hernial orifice, analogous to that occurring in the lower portion of intestine in artificial anus, and in other false passages under certain circumstances. His views are presented in an elaborate letter, found in Chase on Hernia, p. 107, and led to the abandonment of the attempts to produce firmation intentionally.

From this point the efforts of Dr. Chase were directed exclusively to the perfection of the means for producing complete and permanent relaxation of the bowels, and these success may be judged by the few extracts appended to the following consideration of the essential and novel portions of the several apparatuses.

The most important point in each of the instruments of Dr. Chase is the pad or block, by cause upon this depends most essentially the relaxing power. To be fully understood, each block, at a glance and perspective view of it, must be seen; but the following verbal description will give some idea of their appearance. They are all formed of some smooth wood, not too hard or too porous.

For common inguinal hernia, the block resembles a longitudinal section of a long oval cylinder, generated by the revolution of the curve upon its axis, and afterward moulded by force, producing considerable flattening upon one side, and a much more abrupt curvature upon the other. The long axis of the block is designed to make pressure from a point half an inch or more forward, and upward from the internal abdominal ring to near the middle of the external ring. The thicker, or more abruptly curved side, forming a very slightly prominent shoulder, compresses accurately the whole length of the abdominal canal, and the thinner, broader, and more compressed side gently but firmly supports the neighbouring ribs of the abdominal surface, and, with them, the circumference of the hernial orifice, so it is large or small.

For semi-obscure hernia, the block resembles that for common inguinal hernia, the subcostal being much broader, it was supposed to be very strongly compressed upon its upper or broader convexity, until its lower or more sudden curvature is able to arching the base to a great extent, particularly near the middle of the length of the block; so that when the block is placed upon its base and viewed perpendicularly, it presents on one margin a semi-elliptical curvature, and on the other a very obtuse parabolic. The compression of the subcostal segment is much greater towards one extremity than at the other, so that the substance of the block is made to overhang the base very far at the opposite end; and hence the thickest part, as well as the most

overhanging portion, as found at about two thirds of the entire length distant from the thinner extremity. The most projecting part of the overhanging edge, when applied, corresponds with the edge of the pubic hair, exactly at the base of the external ring; but it is prevented from pressing upon the bone by its curvature. The thinner end of the block extends upward and outward nearly to the external ring, and the latter portion of the curved surface supports the overhanging portion of the lower half.

The block for femoral hernia resembles an oval about two and a half inches long by one inch wide, truncated by a plane passing from the extremity of the long diameter at the narrow end, making with it an angle of about twenty degrees to a point distant about two thirds the length of the egg. This figure is considerably flattened on either side of the plane of section, and the overhanging large end of the oval is compressed until it is converted into a broad shoulder parallel with the plane of section, and running the entire width of the wood. When applied, this shoulder presses at first immediately beneath Poupart's ligament; and after the absorption of the subcutaneous fat, which always occurs during the use of these instruments, it is made to dip beneath the ligament, and rise to support the hernial orifice, while the remainder of the oval surface compresses the sigmoid canal, and extends so as to cover the cribiform form at the lesser extremity of the block.

These several forms of block are each fastened by a malleable plate, and are attached to a little steel plate appended to the truss-spring by means of two screws, which pass through a fenestra in the plate, and admit of a variation in adjustment to the extent of about an inch in the direction of the longitude of the block.

The myrioid and ventro-femoral trusses have the steel plate attached to the truss-spring by means of a short, soft iron neck, which, by its flexibility, admits of an expansive adjustment in the direction of the block. In addition to these arrangements, the femoral truss has its soft iron neck elevated, bent at a right angle, and curved with the spring by means of screws passing through a large fenestra in the spring itself, and permitting extensive and accurate adjustment in a direction from or towards the central line.

A plan of adjustment analogous to that last mentioned constitutes the principal peculiarity in the myrioid truss, the spring of which always encircles at least two thirds of the body.

The double truss, a novel and beneficial arrangement, consists of two single trusses, which may be respectively adapted to any combinations of hernia in the inguinal or femoral region. The springs rise over each other behind, the two spring-covers extending but two thirds of the length of the springs from their anterior extremities, where they terminate, each in a strap one of which passing through a cystic hole formed by the loop of the other at its place of attachment to the spring-cover, gives the double spring all the appearance of a single instrument, with infinitely happier means of adjustment.

As success depends upon the accuracy of reduction, a considerable number of blocks of each kind, with slight modifications of relative proportions, are required in practice.

In speaking of these instruments, the committee of the Philadelphia Medical Society remark:—They have effected the permanent reduction

into retention of the intestines in every case of hernia that has come under their observation, without interference to the patient, and often under trials more severe than are usually required by those who wear other trusses; and which would be impatient with any other apparatus known to the community.

The committee feel justified in recommending strong terms the instrument of Dr. Chase to the confidence of the profession, as the best known means of mechanical reduction in all varieties of hernia, and as furnishing the highest chance of radical cure.

In their preliminary report, the committee expressed decided opposition to the employment of trusses in infants. Careful details of the record, and further observation has shaken their opinion on this subject. Several cases, treated at a very early age by the instrument under notice, have proved that they are, in all instances, convenient in infancy. Several instances out of this will be found noted among the evidence in the appendix to this report. The adoption of the trusses to the comfort of children under three years of age, and their secure retention at an age establish their claim to preference over any other mode of treatment. Their applicability within the year has been successfully proved in two cases; and it is certain that the same is adapted to confine the bowels by any form of bandage or compress, than by means of a well-regulated spring and block. The only comparative trial of the softest and best block in use had been resorted to in favor of the latter; but the committee feel bound to give the victory of high-surgical skill and extremely exact attention in dealing with these little subjects.

The time required for the removal of an ordinary case of ventro-femoral or double hernia in the adult appears to be from twelve to eighteen months. It is probable that the best, in certain inguinal hernia, is resolved more in a shorter time; but practice has proved the earlier relinquishment of the truss, even in a very few cases. The relief in double hernia appears to extract somewhat more easily, but all the varieties, however, each more rapid in resolution.

The cases observed include all the usual forms of enlarged hernia, whether resulting from mechanical or physiological causes, and the various instances of double and triple hernia. The complications which have not been presented are known to be very rare, and the trusses themselves feel no hesitation in expressing a strong and, they think, well-grounded hope that a very large majority of the cases of this double hernia will yield to the action of the apparatus of Dr. Chase, when under the direction of persons of high surgical and mechanical talents. —*Final Report.*—[RECEIVED.]

(HERNIA CEREAL. Dr. G. B. B. of New-York, has published, in the N. Y. Journal for 1849, an elaborate paper on this subject, in which are laid out all the means to be used. It is creditable to the author's industry and talent.

In a case of hernia recently lately treated by Dr. March, of Albany, and which occurred after a permanent fracture of the femoral bone of a child, the patient recovered after the removal of the fungus by the scalpel, under a suitable compress and adhesive planter. The following, however, often encountered in these cases, led Dr. March to suggest the application of the atmospheric method in such cases, by means

HYDRIODATE OF POTASSA.

HYDROCELE.

ring a portion of the adjacent scaly, after having prepared the edges of the strapping the fingers for its reception, and the removal of the engaged tissue. There can be little doubt of the adhesions being nearly secured in such a case, and the necessary compression might thus be gained in a much more easy and preferable to the means usually employed for the purpose. It is a novel application of this antiseptic principle, the absorption of which is essential to this success, and would hardly fail of success.—*Review.*

[HIP-JOINT. Dr. John C. Warren, of Boston, has published an elaborate paper on the subject of dislocation of the hip-joint, accompanied by plates, which are well executed, and constituting together a volume of great value to surgeons and medical practitioners. The occasion of the publication was a lecture, in which a respectable surgeon of New-England was involved by a suit for mal-practice, and in which Dr. Warren's testimony had been perverted in the style which is characteristic of a certain class of legal practitioners, who arrogate a right to pervert to critical knowledge in forensic medicine. Dr. Warren has treated the party concerned as he deserves, while he has accomplished himself redress in a manner most becoming to the profession.

Dr. George W. Nares has published, in the 24th volume of the *Amer. Journal*, a entire paper on the diagnosis of injuries of the hip, which is worthy the attention of the surgeon.

In Dr. Nares's *American edition of Lacroix*, p. 162, a description is given of Dr. Physick's method of treating this disease, and in which he had extraordinary success.

Professor Townshend reports numerous instances of recovery from morbid osseous, or hip-joint disease, by an operation which is said to succeed after morbid results have followed the inflammation of the joint. He makes an incision between the gluteus maximus and rectus muscles, and carries it down to the foot, laying open the joint. Immediately after this operation, he states, as the result of his experience, that the pain, distention, and progress of morbid action in the joint all cease, and the patient speedily recovers, in some instances infirmity. He has thus opened the joint in all cases during the acute inflammation, and even after the bone has become carious; and though, in the latter cases, where the bones of the joint have seriously suffered, some inability to use the limb may remain, yet in all instances there is a mitigation of the disease and early recovery. I have no experience in this mode of treatment, but find the failure of all other methods pursued in this formidable disease, even the actual cautery, I regard the suggestion of any method which promises better success, worthy of record, and hence give place to the testimony of Dr. Townshend, who speaks very confidently of the safety and utility of his method.

A surgeon of Philadelphia has lately imputed to the joint for this disease a most unorthodox and unsatisfactory proceeding, and one which no reputable member of the profession will ever imitate.—*Review.*

[HYDRIODATE OF POTASSA. Frequently employed externally, in conjunction with iodine, for promoting the absorption of collections of fluid, and scrophulous and other indolent swellings. The hydropate "adds the solution of iodine in water, and on this second it is given in combination with iodine in aqueous fluids." M. Lacroix

formally is of iodine ʒi. j. hydropate of potassa ʒi. jss., and distilled water ʒi. xij. One fourth portion this solution is to be administered in diluted doses in the course of the day. M. Lacroix forms a bath also of iodine by similar means." (See J. T. Thomson's *Elem. of Materia Med.*, p. 423, col. 2.) I have known the hydropate of potassa, given internally in doses gradually increased up to 10 or 12 grains three or four times a day, dispense success. Friction with the acetum over the abdomen was simultaneously resorted to. That at all the times of the hydropate, its efficacy in syphilis appears the most important as practice. (See *Syphilis and Venereal Disease*, p. 101.)

[HYDROCELE. Dr. Pineau, of Philadelphia, employs a new mode of operating upon hydrocele, by making an incision with a coronal finger, and after a little fluid escapes, he makes pressure upon the tumor until a little bag of the serous membrane containing the contents protrudes. This he draws out with the forceps or hook, and by threadly stripping with the scissors and gentle traction, he removes the greater part of the peritoneal serous tunic. He then sutures the side of the scrotum, including the testis, with strips of adhesive plaster, and a cure has speedily followed. (See *Dagblom's Journal* for July, 1842.)

Dr. March, of Albany, after trying the various methods of operation for the radical cure of hydrocele, has for the last ten years adopted the following plan with uniform success. Holding the tumor in one hand, and making the skin loose, he makes an incision with the scalpel an inch and a half in length through the skin and cellular tissue down to the tunic, selecting its anterior and lower part. He next makes an incision one third less in extent through the tunic, and, after emptying the sac, studies the point of the scrotum by his finger, and injects an ounce of tincture, previously diluted with eight ounces of lime-water. He keeps this mode of treatment up to avoid the accident which has sometimes occurred, of injecting the cellular tissue of the scrotum, and the disastrous consequences of such a blunder.

These are cases in which this disease may be preferable plan, after extensive experience in this operation, by the cautious use of the trocar and cannula, I have inevitably avoided the accident deprecated; nor have I ever any with any important either to the injection of the sac, or the ready escape of the fluid employed. No one operation, however, should be indiscriminately adopted or exclusively preferred.

Dr. J. Watson, surgeon to the N. Y. Hospital, has for several years relied upon compression for the radical cure of this disease, in preference to injections, setons, or the other various methods pursued by different surgeons, after emptying the sac either by the trocar or the latter. He straps the scrotum firmly over the testicle by means of strips of adhesive plaster, and tightens the straps as the tumor diminishes under the pressure, keeping up the compression for weeks, if required. He has found it necessary to repeat the operation in some cases a second time, and occasionally a third puncture has been necessary, but more frequently a single operation, followed by the pressure, has sufficed for the cure. An opportunity having occurred for a post mortem examination of a patient who died eight months after the operation, Dr. Watson found the testis atrophied, and no trace of disease in the tunica vaginalis. From the fact that this patient had

liberated under an extensive complication of disease in the scrofula, testis, and cord, coexisting for a long time with the hydrocele, stimulating carcinomatous induration, it would appear probable that compression on the plan of Dr. Watson may be found useful in the treatment of other affections of the testis and scrotum, and deserves a trial.

This mode of compression by narrow strips of adhesive plaster has been long employed in the Péninsular Hospital, in chronic inflammations and enlargement of the testicle. (See Dr. Norris's edition of *Lectures*, p. 447.)—RANNEY.

[HYDROCEPHALUS. Professor Dugas, of Georgia, reports in the *Southern Medical and Surgical Journal* for 1836, a case of chronic hydrocephalus treated by repeated punctures, which possesses many points of interest for, though unsuccessful in the end for it proved the practicability and haemorrhage of penetrating the brain in such cases, for in this case the brain was punctured seven times, and sixty-three ounces of fluid drawn off during the few months that the child survived the disease. Not the slightest unpleasant effect followed either operation; and on the autopsic examination, sixty-four ounces of a limpid fluid were found in the head, and contained in a sac composed of the expanded cerebrum lining the dura mater, and in which the crura of the seven punctures were distinctly visible.]—RANNEY.

[HYPERTROPHY (from *hypo* and *trope*, signifying an excess of nutrition). This term ought to be restricted to cases in which a part, though increased in bulk, retains its natural organization and structure. It is one of the most common effects of increased activity in the nutrition of textures and organs, and likewise one which may give rise to the most diversified functional disturbance. It cannot always, however, be regarded as a disease. The mere increase of size of a part, unattended with change of structure, or the interruption or disorder of any function by such hypertrophy, cannot be considered as a morbid affection. Thus hypertrophy in a muscle of animal life is not a disease, but in the heart it becomes one of the most serious. (See Andral, *Anal. Pathol.*, t. i, p. 100.) It can hardly come under the denomination of a disease until it interferes with the regular and complete accomplishment of a function. As one of the most distinguished of modern pathologists observes, "That the increased abnormal development of an organ or tissue, denominated hypertrophy, depends essentially on an excess of the nutritive function, appears to be sufficiently demonstrated by the evidence, on the one hand, of an increase of bulk, and the distress, on the other, of any adventitious sort of fluid effusion. The organization and structure remaining unaltered is also further evidence that the increase of bulk is

owing to a superabundant deposition of the natural solid constituents of the affected tissue from an excess of the nutritive function." (See R. Cruveilhier's *Illustrations of the Elementary Forms of Disease*, leucæmia ix.)

1. Many hypertrophies seem to arise altogether from augmentation in the habitual activity of the functions of organs. "The prodigious development and power of the muscles of the superior extremities of the blacksmith, and of the inferior extremities of the stage-dancer, are striking examples of hypertrophy resulting from the influence of the frequent and increased exercise of a function, the effect of which is a corresponding increase of nutrition, and of development of the muscular tissue." The abnormal development of the muscles of profusory action, as those of the heart, bladder, and intestines is likewise often produced of a similar nature, an increased exercise of themselves in general; these organs having been excited and kept up to some extent a morbidly excited state to the very nature of their respective contents." (Cruveilhier, &c.)

2. Some hypertrophies take place as the physiological result of what Andral calls active hyperæmia, either acute or chronic, or, in other words, of a great determination, or of a copious afflux of blood to parts for a number or longer time.

3. Others proceed from some physiological or pathological stimulus, some irritation of the nutritive function creating an excess of it. (See Andral, *Précis d'Anal. Pathol.*, t. i, p. 100.)—C.]

[HYPOSPASIAS or BYPOSPASIAS (from *hypo*, under, and *spas*, to draw). The congenital imperfection in which the urethra terminates at the under part of the penis, seldom not extended sufficiently far forward to reach the right situation of its orifice in the glans. Sometimes there is a vestige of this orifice, sometimes none. Half an inch or more of the urethra may be deficient. About two years ago I was consulted by Mr. Baker, of Stenon, for a case of hypospadias in a young child. In this instance I cut a new passage through the glans, and having established a communication between it and the urethra introduced a silver tube. This was worn for some time, and the little opening having been touched with caustic, a complete cure was brought about. The management of the case was attended with some difficulty, and would not have answered with a piece of Indian gum catheter, which was at first tried; and it was necessary to get Messrs. Weiss to fabricate, at a short notice, a silver tube for the purpose, furnished with a rim, and surmounted by which it could be conveniently fixed. Mr. Liston has sometimes succeeded in completing the passage by turning back a portion of the prepuce, and uniting it without any cast, i. e. with the integumentary outward. (On *Practical Surgery*, p. 476.)—C.]

J.

[JAW-BONE. Dr. J. C. Warren, of Boston, has twice operated the upper jaw; in his first case the patient died three months after in the course of the disease; consequently; but in the other case, remarkably successful, the operation. The same surgeon has removed large portions of the lower jaw seven times with

astounding results, all his patients having recovered.

Dr. Valentine Mott, of New-York, has performed the excision of portions of the lower jaw ten times; and in two instances he has removed this bone at the articulation on one side. In one of these latter cases, the tumour, osteosarcoma,

was nearly as large as the joint's head; and involving the symphysis, as it did, the buccal tooth of the opposite side was removed, and the bone saved through at that point, while on the other side it was necessary to remove it at the articulation.

For Dr. Meit's operation for removing immobility of the lower jaw, see note to article Anchylosis in the text of this edition.

Dr. Meit has removed portions of the upper jaw fifteen times.

Professor Alexander H. Stevens, of New-York, reports a case of osteosarcoma of the upper jaw, successfully treated by the extirpation of the whole of the alveolar maxillary and alveolar bones, and portions of the orbital and sphenoid bones. The account of this formidable operation, with remarks alike creditable to the author's science and humanity, will be found in the N. Y. Journ. of Med. and Surg. for 1840. In this article Ankylosis it will be seen that Dr. Stevens was the first surgeon who ever removed the upper jaw. The operation was in 1823, and Dr. David J. Rees's case in 1824, both of them prior to Mr. Lassar's, of Edinburgh, to whom Mr. Lison attributes this merit by mistake.

Dr. Paul F. Eve, of Augusta, Georgia, has twice removed the upper jaw, and once a large portion of the lower jaw by excision. The latter operation and one of the former were successful. One of the cases in which the upper jaw was removed was osteosarcoma, which was after removal, and carried off the patient.

Dr. McClellan has removed the upper jaw thirteen times, and has performed numerous operations on the lower jaw, removing portions of this bone nine times—twice more than half the bone, including the articulation on one side, and in one instance excising the whole of the lower jaw.

Dr. N. E. Smith, of Baltimore, has successfully amputated the lower jaw; and in one case he removed all that portion between the second molar of one side and the condyle of the other.

Dr. F. D. Mutter, of Philadelphia, has removed nearly the whole of the upper jaw, including both superior maxillary bones, which were involved in that malignant form of disease called epulis, and which originated in the gums. The difficulty has been since remedied by the introduction of a gold plate, to which a row of artificial teeth has been attached, and which conceals the deformity. Dr. Mutter has twice removed a large portion of the lower jaw for tooth-sarcoma, and there has been no return of the disease in either case, although in one of these three years has elapsed, and the other nearly one year since the operation.

Dr. Randall, of Philadelphia, has removed nearly the whole of the lower jaw for an osteosarcomatous tumour, and the patient recovered. (See Amer. Journ. of Med. Science for 1829, p. 188.)

JOINTS, EXCISION OF. This operation consists in the removal of the parts of bones entering into the formation of a diseased joint, together with the whole of the capsular ligament and synovial membrane. "It has a twofold object: the first is to remove a formidable disease, and this might be effected by amputation; the second is to preserve a useful limb, and this amputation could not effect. The fact is worth noting in which the proposal mainly rests, is, that, in the large majority of the alveolar diseases of joints, the bone is either primarily affected, or becomes so secondarily." (See Blackburn in *Guy's Hospital Reports*, vol. 1, p. 271.)

Whether a passage quoted by M. Velpeau from Hippocrates refers to the complete excision of joints, or sometimes practised in the present day, is doubtful. As Mr. Blackburn observes, it may only allude to the removal of the ends of bones in compound dislocations. The record of the first actual performance of the operation is now found in a note appended by Mr. Park, of Liverpool, to a collection of manuscripts on this subject published by Dr. Jeffray, of Glasgow, in 1800. It is there stated that, in 1702, Mr. Filkin, of Northwich, in Cheshire, in a case of diseased knee, removed the patella, along with the articular extremities of the femur and tibia. A similar operation was performed on the shoulder in 1707 by M. Vizarotti, of Montpellier. (*Cher. de Chir. Pratique*, Montpellier, 1812. In 1708, Mr. White, of Manchester, planned the diseased head of the humerus, and with such success that the patient could afterward carry heavy weights, and resumed every motion of the arm. (See White's *Case and Obs.*, Phil. Trans., vol. 17.) In 1771, White's practice was imitated by Mr. Bent, of Newcastle, and a few years afterward by Mr. Orpet, of Chester. (See Phil. Trans., vols. 176 and 181.) With the exception of Mr. Filkin's case, however, in all these examples only one articular surface was removed. (See *Amputation*.) The merit of suggesting the operation, as defined in the first sentence of this article, unquestionably belongs to Mr. Henry Park, of Liverpool. In a letter to Mr. Pett, dated 1792, Mr. Park made the proposal of totally extirpating many diseased joints, by which the limbs might be preserved, with a share of motion that would still allow them to be very useful. In order to learn whether the popliteal vessels could be avoided without much difficulty in the excision of the knee, Mr. Park made an experiment on the dead subject. An incision was made, beginning about two inches above the upper end of the patella, and extending about six below its lower part. Another one was made across this at right angles immediately above the patella, down to the bone, and nearly half round the limb, the leg being in an extended state. The lower angles formed by these incisions were raised, so as to lay bare the capsule ligament; the patella was then taken out; the upper angles were raised, so as fully to denude the head of the femur, and to allow a small catgut to be passed across the posterior flat part of the bone immediately above the condyles, care being taken to keep one of the flat sides of the point of the instrument quite close to the bone all the way. The catgut being withdrawn, an elastic annula was introduced in its place, to guard the soft parts while the bone was sawn. The head of the bone thus exposed was carefully dissected out; the head of the tibia was then, with care, turned out and sawn off, and as much as possible of the capsular ligament dissected away, leaving only the posterior part covering the vessels, which, on examination, had been in very little danger of being wounded.

The next attempt was on the elbow; a simple longitudinal incision was made from about two inches above to the same distance below the point of the olecranon. The integuments having been raised, an attempt was made to divide the lateral ligaments and subdivide the joint, but this being found difficult, the olecranon was sawn off, after which the joint could be easily dislocated without any trifling incision, the lower extremity of the os humeri being cut off, and

afterward the heads of the radius and ulna. This appeared an easy work; but Mr. Park concludes the case will be difficult in a diseased state of the parts, and that a crucial incision would be requisite, as well as involving the humerus above the condyle, in the way done with respect to the thigh-joint.

Mr. Park first operated, July 3, 1811, on a strong, robust sailor, aged 32, who had a diseased knee of ten years' standing. The man's sufferings were daily increasing, and his health declining. Mr. Park wished to avoid making the transverse incision, thinking that, after removing the patella, he could select his object by the longitudinal one; but it was found that the difference between a healthy and diseased state of parts deceived him in this expectation. Hence the idea was relinquished, and the transverse incision made. The operation was finished exactly as the one in the final subject related above. The quantity of bone removed was very little more than two inches of the femur, and rather more than one inch of the tibia. The only artery divided was one on the front of the knee, and it ceased to bleed before the operation was concluded, but the eplysis of the bones bled very freely. In order to keep the refractory integuments from falling inward, and the edges of the wounds in tolerable contact, a few squares were used. The dressings were light and superficial, and the limb was put into a cast sufficiently long to receive the whole of it, from the ankle to the insertion of the gluteus maximus.

I shall not follow Mr. Park through the treatment. Suffice it to remark that the case gave him a great deal of trouble, and that it was attended with many embarrassing circumstances, arising chiefly from the inability of keeping the limb in a fixed position, the great depth of the wound, and the abscesses and sinuses which formed. On the other hand, however, the bad symptoms were not at all dangerous. But the patient was obliged to keep his bed nine or ten weeks, and it was many months before the cure was complete. The man afterward went to sea, and did his duty very well.

Subsequently to the publication of the letter to Mr. Pitt, another excision of the knee was performed by Mr. Park on the 23d of June; but the event was unsuccessful, as the patient lingered till the 10th of October, and then died.

In 1783 the year following that of the publication of Mr. Park's pamphlet, the subject was brought before the Academy of Surgery in France by M. Moreau. In 1784, this surgeon excised the head of the humerus and the glenoid cavity. In 1792 he operated on the elbow, and he and his son several times excised the articular surfaces of the knee, ankle, shoulder, elbow, and wrist. Their example was followed by Desmeunier and Dupuytren. In 1800, Maudslayi, of Groningen, cut out a knee-joint. (See *Wharton, Dict. de Articul. Extremis*, 1810.) In 1810, M. Moreau, of Paris, performed the excision of the elbow. (See *Edinb. Med.*, 1839.) In 1823, the same operation was executed by Mr. Crumpton, who has likewise excised the knee with success (see *Dublin Hospital Reports*, vol. i. &c.) and in 1835 by Mr. Syme, who has excised the elbow in fourteen cases. The operation has since been suggested for these three joints, by Mr. Syme, of Otago, in Yorkshire; by Dr. Simpson, of Edinburgh; by several correspondents of the Glasgow Infirmary (see *JP. Fane's Case Reports*, &c.); by Mr. C. Adam Key (see *Blackburne's Key's Hope-*

al Reports, vol. i.), and in University College Hospital, by Mr. Liston. The operation has also been executed by M. M. Charrière and his pupils. (See *Vulpian, Nouv. Élév. de Méd. Opér.*, t. i., p. 553.)

In the first elbow case, operated upon in 1779 by M. Moreau, the patient went on so favourably that he was allowed to go about whenever he pleased, with his arm supported in a cast. The limb was at first powerless, but it slowly regained its strength, and the man could ultimately throw corn with it, and hold the plough. Seven months after another operation of the same kind performed by M. Moreau the patient was completely well, and in two years more the flexion of the arm was very distinct. In another case the patient got well in six weeks, and in three months more joined his regiment.

In all Moreau's cases, the function and extension of the forearm were preserved, which circumstance, no doubt, depended very much on the insertion of the nerves not being destroyed. After the excision of the knee, however, the bones grew together.

Excision of the Elbow-joint.—The following is the plan of operating recommended by Mr. Syme, which is nearly the same as that practised by M. Moreau. The patient should lie with his legs downwards, so as to prevent the posterior surface of the joint. The incision, with a straight, narrow, sharp-pointed knife, makes a transverse incision into the joint, close above the olecranon, and extending from the inner side of this process to the external condyle. In doing this care must be taken to avoid the ulnar nerve, which lies close to the inner side of the olecranon; and, with this view, the safest plan is to introduce the knife perpendicularly into the joint, with its hand directed towards the nerve. At each extremity of the transverse cut, the surgeon must make an incision about an inch and a half long, both upward and downward, in the line direction of the limb, as in a figure two separate flaps, and give to the wound the shape of the letter H. These flaps being detached from the adjacent parts, the olecranon may be easily removed with the saw or pliers, after which an difficulty will be experienced in raising the lateral ligaments, making the end of the humerus protrude, and sewing it off above the condyles. The head of the radius may next be cut away with pliers, and then the excision of the sigmoid cartilage of the ulna, left after the removal of the olecranon, may easily be accomplished with the same instrument. "It might, he thought better to take away all the ulna that required excision at once; but the attachment of the brachial vessels to the sigmoid process renders this very difficult, especially if it is attempted before the bone space offered by the removal of the other bones has been obtained." (See *Syme's Principles of Surgery*, p. 214, vol. 2, 2nd ed., 1837; also, *Treatise on the Excision of Dislocated Joints*, 8vo, Edinburgh, 1831.)

M. Moreau begins the operation by making an incision, between two and three inches long on each side of the joint, commencing about two inches above the condyles and carried down in the direction of the ulna to the height. These two wounds were next connected by a transverse incision through the skin and tendon of the biceps, immediately above the olecranon, and the flaps were then raised.

As soon as the flaps have been raised, Dupuytren recommends us cautiously to open the sheath of the ulnar nerve, behind the internal condyle,

and the nerve to be kept inward and forward by an assistant with a bent probe, at the period when the humerus is to be divided. The preliminary removal of the clavicle, as directed by the same eminent surgeon, is regarded by M. Malgaigne as unnecessarily complicating the operation. (See *Monat. de Méd. Opér.*, p. 243, ed. 2.)

When the flaps have been dissected, and the axillary nerve drawn forward in front of the inner surface, the undivided soft parts are to be drawn in the same direction; the muscular fibres then detached from the bone with the point of the knife; a spatula or flat piece of wood introduced in front of the humerus, and the bone sawn through from behind forward. The lower pole of it is then to be inclined downward and backward, and separated from all its connections, the anterior, external, and internal lateral and posterior ligaments being cut through in succession. As a thick muscle, the *testis internus*, is interposed between the humerus and the artery, the avoidance of the vessel becomes attended with any difficulty. If it be necessary to carry the incision down to the foramen, as far as the laceration of the artery, this vessel is more exposed to injury. It is of great importance, if possible, to saw the skin above the insertion of the *brachialis*, and more especially the *radialis*, above that of the biceps. Mr. Syme, however, has divided the biceps lower down, and yet the use of the hand was preserved. (See *Volkmann's Atlas*, *de Méd. Opér.*, t. i., p. 563.)

Mr. Liston prefers a single perpendicular incision at the outer side of the joint, and the *quadratus* cut. An incision is made on the radial side of the ulnar nerve, and in the direction of the bone, by passing the point of the knife through the *ligamentum* and *flexor* of the triceps to the back of the humerus, and carrying it in contact with the ends of that bone and the glenoid for about three inches. Another incision, commencing over the outer condyle of the humerus, and penetrating to the articulation, is made to fall at the middle of the at right angles. The two flaps are reflected, and the soft parts, with the nerve, are turned over the outer condyle. The ends of the bones, but slightly retained by their ligaments, are turned out of the wound by bending the forearm. During the course of the bone, the *glenoid* is of use in protecting the nerve or other soft parts. A partial ankylosis will be found occasionally to have formed, and then the saw and cutting forceps may be called in. In operating upon young subjects, the cutting forceps may sometimes be used in preference to the saw, the bones being soft, and extensive removal not demanded. After turning the edges of the wound together with three sutures, Mr. Liston applies wet lint to the wound for a few hours, and then strips of plaster; the sutures are soon removed, and the tepid-water dressing employed. After a week or two, the limb which has been kept bent on a pillow, is secured in splines, and supported in a sling. (See *Liston on Prost.*, Surgery, p. 140.)

The above point, Mr. Blackburn observes, has been so frequently noticed that it would be alike useless and tedious to present an analysis of each operation. The two *Messieurs* secured three cases, all successful; and state that they had operated several other times, and always with fortunate results. M. Roux recalls three cases, which have terminated favourably, and one which terminated unfavourably. (Review Med., 1833.) Mr. Syme numbers no less than nineteen opera-

tions, of which only two have been attended with unhappy results (*On Diseases of Joints*, &c., in *Ed. Med. and Surg. Journ.*, for 1832, 33, 4-5); and Messrs. Key, Crumpton, Chatterlain, Spence, Simpson, and one of the surgeons to the Glasgow Infirmary, can each furnish a successful case. The operation is said to have been performed with fortunate results by Messieurs in Italy, by Eschschütz in France, and by Mr. Bond of Newcastle. Altogether, there are 31 of which histories have been given. Of these, there have been fatal; one patient dying at the end of five weeks, from the combined effects of phlebitis and of an enormous abscess of the hip; and the two others from septicæmia more immediately connected with the operation. Of the remaining twenty-nine, nearly all recovered the motion of the joint: in three or four a retained effusion and rigidity, principally from neglect of the instructions given as to exercise. In the one of these cases, the constitutional irritation that followed plagues. All the patients had been suffering for many months, or for years; the most approved methods of treatment had been tried unsuccessfully, and in many instances, extensive suppuration had recommended amputation. In a few, the recovery was very rapid; but in the majority, some months elapsed before the joint could be pronounced to be quite sound and set into small spaces smoothed open, though exercising no employment. The patients, in general, returned to their previous occupations. One of M. Roux's was occasioned to see his cousin thrashing, ploughing, &c.; and one of Mr. Syme's wrote to him, two or three years after the operation, to say that his arm was strong enough to carry eighteen or twenty pounds weight with ease; that he could raise six or eight pounds to his head; and that he could write and perform any ordinary work, "so that no person would know (his secret) whether I had my elbow or was without it." &c. At the meeting of the British Association, held at Edinburgh in 1844, Mr. Syme produced several persons on whom the operation had been performed, along with the position of bones removed, and Dr. Hodgkin, that the other members present were surprised and gratified by the strength and mobility which the new articulations had acquired. (*Gag's Hosp. Reports*, vol. i., p. 231-233.)

There is just, in reality, a new joint with a capsule formed, but the ends of the bones become connected by ligamentous fibres, and a sufficiently firm substance is produced to serve as a fixed point for the muscles, which execute the flexion and extension of the humerus. (See *A. Volkmann's Atlas*, &c., t. i., p. 564.)

Besides the cases above alluded to, Mr. Liston has had others which proved successful, and one of them in University College Hospital.

In general, no vessel requires a ligature. One patient, under M. Roux, however, had a secondary hæmorrhage—a solitary occurrence.

Mr. Syme recommends the wound to be closed with sutures, and a long figure of 8 bandage to be applied to support the limb, "which should be bent at a right angle, and to prevent the ends of the bones from moving, or pressing againstly on the soft parts." Rigid scars of four or more to be made in the neighbourhood. "I do think, after the first two or three days, will feel himself most comfortably in the erect position; and when the inflammatory tension begins to subside, he should gently, but diligently, exercise the limb, so as to preserve the mobility of the elbow." (See *Syme's Principles*, p. 216, ed. 2.)

In the five operations which Mr. Liston has performed on the adult, he has aimed at bringing about a sort of ligamentous ankylosis, by steadily keeping the parts for a long while by means of leathern straps with the femur at a right angle. On the contrary, in young patients, he says, "the motions of the part may be encouraged, and with every chance of their becoming free and strong." (*On Potential Surgery*, p. 138.)

Excision of the Knee-joint.—In a knee-joint, Mowat, the father, operated as follows: He made a longitudinal incision on each side of the thigh, between the crutch and the femur of the leg, down to the bone. These incisions began about two inches above the condyles of the femur, and were carried down along the sides of the joint till they reached the pita. They were united by a transverse cut, which passed below the patella oblique to the bone.

The flap was raised, but the patella attached to it, being dissected, was dissected out. The limb was then bent, so as to bring the condyles of the femur into view. As it was desired to cut them from the body of the bone before dislocating them, everything adjoining to them behind, where they joined the body of the bone, was separated, and at that place the forefinger of the left hand was passed through in order to press back the flesh from the bone, while the saw was used. The knee having been bent, Mowat drew the cut piece towards him, and easily detached it from the flesh and ligaments.

The head of the tibia was laid bare by an incision nearly sixteen lines long, made on the spine of that bone. The first lateral incision on the outer side of the knee was extended nearly as far down on the head of the tibia. Two were obtained one flap, which adhered to the flesh, filling up the articular space, and another triangular flap formed of the skin, covering the outer surface of the tibia, which lobe was if necessary exposed before the saw could be applied.

Upon raising the outer flap, the head of the tibia came into view; and, after being separated from its attachments, was cut off with a small saw. The inner flap was then raised, and the head of the tibia, having been separated from the muscle behind, was saved also. (*See Mowat & Co. Op. postérieurement à la Résection des Articulations affectées de Cancer*, Paris, an. XI.) Some cases and remarks in favour of the excision of diseased joints have been published by Mr. Erastus. (*Phila. Hospital Reports*, vol. II., p. 163, &c.) He has remarked with success one knee and one elbow. Another knee operation may be set down as a failure, no union having taken place, and a suppuration discharging contents to the bone until the patient's death, three years and two months after the operation. Respecting the plan of operating on the knee, he concludes thus: "I am satisfied, from repeated trials on the dead subject, that the operation can be most safely and rapidly executed by separating the condyles from all their attachments previously to sawing the bone. As soon, therefore, as the flap covering the patella is turned upward, the edge of the knife should be carried round the condyles close to the bone, so as to divide all the ligaments which connect the femur with the tibia. The tibia goes then, with great ease, is pushed backward, and as much of the protruding condyles can be removed as the operation may think necessary." (*Ibid.* ch. p. 218.)

It does not appear necessary to insert in this

work the account of cutting out the ankle-joint, an operation which will never be extensively adopted; nor shall I add anything more concerning the mode of removing, in a similar way, the shoulder-joint. In treating of amputation in this situation, I have already said enough, and whenever wishes for further information respecting this practice must refer to Dr. Wilson's work, entitled "*Cases of Excision of Cancerous Joints*," Glasgow, 1806. Dr. Jeffrey recommended a particular, and, indeed, a very expensive saw for facilitating the above operation. The saw alluded to is constructed with joints, like the chain of a watch, so as to allow itself to be drawn through behind a bone, by means of a crooked needle, like a thread, and to cut the bone from behind forward, without injuring the soft parts. In placing the saw under a bone, its cutting edge is to be turned away from the flesh. Handles are afterwards hooked on the instrument.

According to my notions of the treatment of diseased joints, so long as the patient's strength is not exhausted by the irritation of the local disease, amputation dictates the propriety of preserving in an attempt to save the affected limb, &c. Will a patient, greatly reduced by hectic symptoms, be able to recover from so much and bloody an operation as the dissection of the whole of the knee-joint out of the limb? If some few could escape with life and limb preserved, would the talk of persons trained in this matter have the same good fortune? I cannot admit that the extraction of the whole of so large an articulation as the knee can be compared with the operation of amputation in point of simplicity and safety. However, it is not on the difficulty of performing the former that I would found my objections; but I believe that any man possessing a tolerable knowledge of the anatomy of the leg might venture to achieve the business. The grounds on which I withhold my approbation from the attempt to cut out the knee are the following: 1. The great length of time which the healing of the wound requires. Whenever peruse the case of Hector McLaughlin will find that the operation was performed on the 23 of July, 1821, and that it was February 28th of the following year before all the subsequent discharges were perfectly healed. The entire of thirteen very nearly eight months! Mr. Pink describes the patient to be a strong, robust sailor, and gives no further particulars concerning the state of his constitution than that his health was declining. I entertain little doubt, that, if the excision of the knee had been performed in that state of the health in which amputation becomes truly necessary, the man would not have survived the illness arising from the operation. The only other case in which Mr. Pink extirpated the knee ended fatally. In the history related by Mowat, there seemed, indeed, to be considerable liability. The patient endured the last surgery uncomplainingly, so severe an operation; and, afterwards, would confess, the patient was in, with a sickle and Mowat asserted he would be able to walk some weeks in shallow boots or sandals. The young man in the mean time was attacked by an epidemic dysentery, and died. On the 21st of October, 1809, Walker extirpated the knee-joint of a pregnant woman in the Hospital at Strasbourg; but she died of typhus on the 8th of the following February. He observes that the operation is much facilitated by removing the ends of the femur and tibia in their detached state. (*See*

Dis. th. Articulis corporis auctore G. H. Wucherer, 1810.) 2. Even supposing the extension of the knee to be followed by all possible success, is the advantage of having a mutilated, shortened, stiff limb, in lieu of a wooden leg, sufficiently great to induce any man to submit to an operation beyond a doubt infinitely more dangerous than amputation? I think not. The practice is at present nearly exploded in this country; but I hear every now and then of its being adopted at Paris, and Mr. Crompton has thought it worthy of revival. The difficulties of his operations, however, and tediousness of the after-treatment, and, in particular, the general course and termination of one of his two knee-cases, as represented by himself, are sufficiently discouraging. No doubt more limbs might be saved by this practice than

by that of amputation, but more lives would be lost. On this principle, I see no reason for preferring excision of the knee to amputation. Many interesting observations on the extirpation of various thoracic joints may be found in the above-mentioned dissertation by Wucherer, and in the analysis of it by Laugewieck (*Bücher, für die Chir.*, b. 3, Göttingen, 1811); likewise in Mr. Blackmore's paper, in *Guy's Hospital Reports*, vol. i.

The latter gentleman's conclusion, from a review of nearly all the cases on record, is, that excision is admissible in the shoulder and elbow; that it is admissible, though of doubtful utility, in the ankle; and that it is inadmissible, except under very peculiar circumstances, in the wrist, hip, and knee. (*Op. cit.*, p. 294.)—C.]

K.

[KREOSOTE (from *κρεας*, flesh, and *ωσος*, I eat). A new principle, discovered by M. Buchsbaum in 1801 is pyroigneous acid and all the base, and is named from its property of preserving animal matter? According to this gentleman, it is of service in gastric, cancerous ulcers, rheumatic pains, and other diseases. It appears from Dr. Ellulson's researches that it has considerable power in checking vomiting, even that attending Asiatic cholera. He also found it of use in phthisis, epistaxis, diabetes, and neuralgia. "Of its external application (say he) I can speak favourably. When an ulcerated surface has required a stimulus, or when a slough, or unhealthy, perhaps offensive discharge existed, I have seen it of great utility. As it prevents or arrests putrefaction, and removes all taint in dead matter, we cannot be surprised at its restoring the offensive nature of discharges, whether from mucous membranes or ulcers, and preventing the injurious effects of diseased animal matter upon the part with which it is in contact. When the contents of the intestines have been very offensive, I have ungrudgingly assented with advantage, and I have employed it as a wash in mercurial salivator, as well as ulcerated, and in fæces of various parts of the system. I have seen foul ulcers become clean, and ulcers of long standing have sometimes healed rapidly on its application." Dr. Ellulson bears testimony, also, to its efficacy as pruritus pedis, toothache, and purpura. (*See Med. Chir. Trans.*, vol. xix, p. 217.) For external use, he says that from half a drop to two or three, diffused in water by means of pillage, will usually be sufficient, though

its application must be very frequent. I have tried it in a few examples of phagedenic ulceration in University College Hospital, and occasionally with success. I have known it used in the proportion of from three to eight or ten drops in each ounce of water. If given internally, it is best to begin with one or two drops, and increase the dose very gradually. In this way, one lady under Dr. Ellulson's care was able at last to take fifty drops as a dose.

It is alleged that kreosote, as an external application, is advantageous in preventing the contraction of cicatrices, and that it is therefore useful in burns. (*See Sir F. Smith in Dublin Journ. of Med. Science*, vol. xii, p. 217.) "In different eruptions of a scaly nature (says the gentleman), kreosote has been found decidedly useful, and perhaps the most favourable have followed its application to ulcers and solutions of continuity, having a venereal or scrophulous origin. From its known antiseptic properties, it has been recommended in gangrene." He also refers to its use as external and internal hemorrhages. Sir F. Smith tried it with success in phagedenic ulceration of the penis, disease of the septum narium, fetula in ano, tinea capitis, and cancerous ulcers. Sometimes he employed one part of kreosote to sixty of water; sometimes one of kreosote to sixty of acetic acid; and occasionally he brushed the edges and surface of ulcers with pure kreosote. His observations lead him to expect that kreosote would prove useful in cancerous cancer and chronic ulcers of the uterus. Further observations on kreosote will be found in *Edinb. Med. and Surg. Journ.*, No. cxxii.—C.]

L.

[LARYNGOTOMY. It consists either in puncturing the crico-thyroid membrane, as first proposed by Vicq d'Azy, or in dividing, at the same time, the thyroid cartilage in the middle line, as first suggested by Desault, or in dividing the cricoid cartilage and upper rings of the trachea, as originally recommended by Boyer. The last operation is sometimes termed *hæmo-cricotomy*. To these methods it is to be added that of

making the opening through the hyo-thyroid membrane, as proposed by M. Malgaigne. 1. The first modification of laryngotomy consists in opening the anterior part of the larynx in the small triangular membranous space which lies between the thyroid and cricoid cartilages. The thyroid cartilage is exposed by dividing the skin and subcutaneous tissue into the posterior surface of it, along the middle line, and at its lower third,

are inserted the thyro-arytenoid muscles and the chordæ vocales. The patient should be in the recumbent posture, with the head thrown back, so as to render the prominent Adam's prominence. The incision should begin over the upper part of the thyroid cartilage, and be carried down to the cricoid cartilage. The crico-thyroid membrane having been exposed, the crico-thyroid artery is to be depressed with the nail, and the membrane opened directly above it. A probe-pointed bistoury, or the blade of a pair of long-pointed scissors, may then be introduced, with the edge turned upward, and the cartilage cut in the direction of the middle line, without inclining to the right or left, for fear of injuring the chordæ vocales. (See *J. F. Malgaigne, Man. de Méd. Opér.*, p. 388, ed. 2.)

Of the operation performed in the crico-thyroid membrane, Sir Charles Bell entertains a favourable opinion. He directs us to slit up the membrane, and open the incision with the handle of the knife, when the patient will immediately breathe with ease. Here, says he, there is nothing to alarm the most timid operator. No great tough veins are opened, the cut is made above the thyroid gland, and above the accompanying branch of the thyroid arteries. The part is strongly marked by the prominence of the thyroid cartilage above, and the ring of the cricoid cartilage below. "If this occurs be temporary, a simple slit of the membrane will be found sufficient. If necessary, a transverse cut will afford any degree of opening. If a round hole be desired, the four corners left by the incision may be snipped off; or the edges of the opening may be kept steady by means of the divided wire of a catenar, the middle part of which lies on the wound, while the ends are kept round the neck, and tied with a ligature behind." In Sir C. Bell's cases, less annoyance was caused by this contrivance than the tube.

2. *Laryngo-tracheotomy*.—As the lower part of the incision implicates the trachea, the lachryms of the thyroglottic must be cut; but the pharynx of thyroid veins should, if possible, be avoided. Higher up, the knife passes through the skin, the fascia, the cricoid cartilage, and the crico-thyroid membrane, on which a small artery runs transversely. This it is desirable not to wound. The patient's head and neck being inclined back, so as to render the larynx prominent, an incision is to be made from the lower edge of the thyroid cartilage, and extended downward an inch and a half, so as to bring a portion of it over the trachea. As soon as the crico-thyroid membrane has been exposed, the artery is to be pushed upward with the nail of the left fore-finger; the hæmorrhoid opened below the vessel; and then the cricoid cartilage, and three or four of the upper rings of the trachea, divided from above downward. (See *J. F. Malgaigne, Op. cit.*, p. 388, ed. 2.)

3. *Laryngotomy through the Thyro-hyoid Membrane*.—This method has been proposed by M. Malgaigne. A transverse incision, about two inches in length, is made directly below the thyroid lobe. With the curved stroke of the knife, the platysma, and the lower half of each sternohyoid muscle, is divided. The point is then directed upward and laterward, and the thyro-hyoid membrane divided in the same transverse direction, together with those fibres of it which proceed to the epiglottis. The mucous membrane is thus exposed, and at each extremity it protrudes through the wound. It is now taken

hold of with forceps, and divided, whereby the epiglottis is brought into view; and, being fixed into the wound by the breath, is to be taken hold of with forceps, or a hook, by which means the whole of the interior of the larynx will be exposed to view, and the instrument passed into it under the guidance of the eye. (See *Manual de Méd. Opér.*, p. 402, ed. 2.)

With respect to the advantages of laryngotomy, Mr. Poirer pronounced it to be "an operation unattended either with difficulty or danger, and will answer every purpose when the cause of obstruction is seated in the mass glutinosa, or above it." (On the Surgical Pathology of the Larynx, p. 265.) A single opening in the crico-thyroid membrane would suffice for the introduction of a cannula, for the purpose of enabling the patient to breathe; but for the extraction of foreign bodies, it would be necessary also to cut the thyroid cartilage. The fact that extraneous substances, when they are loose, are almost always lodged in the upper part of the larynx, proves that laryngotomy, in such cases, must certainly be most advantageous; and, according to Desault, even when the foreign bodies are lower down in the trachea, they may, in general, be most easily extracted with the aid of a pair of curved forceps.

"Of the three situations (says Mr. Lawrence) in which it has been proposed to make the opening, viz. in the thyroid cartilage, between that and the cricoid, or in the trachea, I consider the first as the least eligible. Besides the objection from the configuration of the cartilage, and the danger of wounding or otherwise injuring the chordæ vocales, there is the inconvenience in the case of a large larynx arising from the swelling and thickened state of the membrane, which may actually impede the passage of the air. I am not aware of any objection to a transverse opening between the thyroid and cricoid cartilages. The prominence of the former in the neck serves as a guide to the part which should be used. Whether laryngotomy or laryngostomy ought to be selected, must, of course, depend on the nature of the case. In cases of cricoid, the proximity of the inflamed parts would be an objection to laryngotomy; while, in examples of large bodies within the glottis, this operation may generally be most advisable. It is almost to that of making one mode of opening in different cases." (See *Medico-Chir. Trans.*, vol. vi., p. 248.)

Laryngotomy, in King's College's manner, seems to M. Velpeau to be most easily performed, and to have the advantages of implicating no part of importance, and of leaving the pharynx unaltered; but when foreign bodies require extraction, the opening is too small for the introduction of instruments, and it would not admit a cannula of sufficient size to let respiration be freely carried on. Hence M. Velpeau thinks liberally of the plan of opening the larynx more extensively, especially as no artery or vein of importance is in danger of being wounded. This, he says, is the only method of exposing foreign bodies, which mostly lodge in the mass glutinosa, and of getting at polypus and other growths within the larynx. Although an injury of the chordæ vocales (says he) is easy to avoid, and of little consequence, yet although the voice is lost, some acquired by this operation, that others, yet it merits preference only in the cases specified, and when the thyroid cartilage does not contain too much phosphate of lime." (See *A. Velpeau, Nouv. Éléms. de Méd. Opér.*, s. ii., p. 507.)

As for laryngo-tracheotomy, which usually

leaves the thyroid gland un injured, but wounds the crico-thyroid artery. Mr. Velpeau observes that it does not, like the method of Desault, enable the surgeon to see to the bottom of the larynx; and while it is too far from the larynx to be convenient for the extraction of such foreign bodies as are not movable, it is but rare the guide for the safe employment of a trachea. Hence, except when Desault's plan is especially indicated, Mr. Velpeau generally guides tracheotomy.

Dr. M. Malgaigne's operation I cannot speak from experience; but, as being less simple than a division of the crico-thyroid membrane, or of this and the thyroid cartilage, it seems not to be entitled to general adoption, even where an opening very high up is desirable. Whatever considerations it may have in its favour, its external effects, depend upon its bringing the interior of the larynx more completely into view than is effected by other plans.—C.

[Dr. Meek, of New-York, has opened the larynx between the thyroid and cricoid cartilages, for the purpose of admitting air in acute and chronic laryngeal affections, with great temporary relief. In all the cases have been ultimately fatal. This is the candid confession of those who have admitted the experiment in untractable cases of croup, for which some of the tracheotomic surgeons have so highly commended its utility and success.—Russe.]

[LIGATURES. Dr. Kay, of Georgia, employs exclusively ligatures made of the tendon of which the door, when he exports water by the first intention; they were originally suggested by Dr. John Bellinger, of Charleston, South Carolina. In all cases where suppuration is anticipated, neither these nor any other form of animal ligatures can be relied on. Silk ligatures are universally employed in America in such cases.—Russe.]

[LITHOTOMY. The first and most important step preparatory to deciding upon this operation is the introduction of the sound, which should be of steel, and the handle of which should be smooth, so as to enable the surgeon to detect more readily the final touch of the calculus. The importance of certainty in making out our diagnosis in cases of stone in the bladder, will be appreciated when we are reminded of the mistakes committed on this subject by the most eminent of the profession. In Dr. Norris's edition of Liston's Practical Surgery, several examples of these mistakes are recorded, in which lithotomy was performed when there was no stone; and, on the other hand, patients have been postponed, after frequent bleeding, to have no stone, and, dying of the disease, very large calculi have been found in the bladder. The great Cleveland lithotomized in three cases and found no stone; Dupuytren, Roux, Desault, and many other European surgeons, have committed the same error. It has several times happened in America, and in the hands of men of established reputation. Even Dr. Physick, that when there never was a more cautious practitioner, came very near committing this sad blunder; for he says, "I wounded a patient, and had no doubt but that he had stone; his health, however, was bad, and I did not operate. He died soon after, and, upon examination, we found no stone."

In addition to the several directions given upon this subject in this Dictionary, the endoscope is found to be an invaluable aid to diagnosis in those doubtful cases in which the surgeon finds it difficult to feel the stone. This instrument I

have had occasion to use in two instances of this character, and we were enabled to hear the crystals by placing the stethoscope upon the perineum, over the pubes, and even upon the scrotum, when the sensation was infinitely not to the sound, and wholly invisible without the mode of auscultation. In both these cases the operation was performed as reliance upon this collector of the presence of the stone, and, as the result proved, with propriety. In one of these, the prostate gland was greatly enlarged previously, and the calculus occupied a site immediately behind it, from which I failed to dislodge it by changing the position of the patient, as suggested by Dr. Physick, placing him upon his head.—So also, the finger being introduced into the rectum while the sound was in the bladder, could not sufficiently elevate the calculus as to make it distinctly felt. Occasionally the convex portion of the sound would touch the calculus, and yet the next moment it was impossible to find it. But with the stethoscope the diagnosis became easy.

This object of recognizing with certainty the presence of the stone, is not, however, the only result which should be sought in sounding; but we can frequently ascertain the number of stones, their size, consistency, and sometimes their configuration, and whether rough or smooth, in several of which inquiries the stethoscope will be found useful, and deserves more attention than has hitherto been bestowed upon it, not only in this case, but in fractures, as well as in probing for foreign bodies in the ear, nostrils, or other cavities, and also in gunshot wounds. Cystitis may to this recognized in obscure cases with great readiness and certainty.

Dr. Physick's valuable improvement in the probe, so highly appreciated by practical surgeons, does not appear to have attracted attention in Europe; it consists in having a movable blade, which can be removed for the purpose of sharpening. The same gentleman recommends the introduction of a large gum-elastic catheter into the bladder through the urethra, together with a long slip of lint into the wound between the lips of the prostate, in cases of secondary hemorrhage occurring after lithotomy. The pressure thus produced upon the wounded arteries of the prostate and the vesicæ vesicales may be continued for several days, and until suppuration commences; the urine meanwhile passes off by the catheter instead of flowing through the wound. Dr. Gibson has twice had occasion to adopt this expedient of Dr. Physick, and in both instances he thinks the patients would otherwise have perished.

Dr. Gibson has performed the lateral operation over fifty times, and has lost but six of his patients.

The high operation above the pubes was performed by Dr. Gibson for the first time in America, and has since been repeated with success by Dr. McCallister, of Philadelphia; Dr. Carpenter, of Lancaster; and Dr. Van Vahala, of Lewisburg, Pennsylvania.

A case of calculus of so large a size that it could not be broken with the forceps occurred to Dr. Goddard, at Charleston, some years since; and, after having cut down into the bladder, the operation was abandoned, it being found impossible to break or to extract it, because of its enormous size. The wound healed up, and the man walked to Carlisle, Pennsylvania, where Dr. Gibson operated with the like result a second time. After his recovery he walked to Philadelphia.

him, when, for the third time, Drs. Gibson and Physick performed the operation, and, finding the stone almost to fill the bladder, Dr. Gibson applied a drill-bit as inch-worm, and made an opening large enough for the blade of the forceps; when, with the other, he soon quarried the stone and removed it. His patient recovered in two weeks, and again walked home, as Dr. Chapman remarks, "a stone lighter."

Mr. Cooper has made valuable additions to his article on the subject of lithotomy, which are here inserted.

LITHOTOMY. It is correctly noticed by Sir Benjamin Brodie, that the symptoms differ, 1st, according to the size of the stone, the smoothness or roughness of its surface, and its general form; 2dly, according to the quality of the urine. If the urine be unusually acid or very alkaline, and deposits the triple phosphate, it will be stimulating; and the symptoms of stone will thereby be aggravated; 3dly, according to the state of the bladder. Nothing aggravates the symptoms so much as inflammation of the mucous membrane; this increases the sensibility of the bladder's benighted fold, and causes a small stone to produce much greater distress and pain than a large one under ordinary circumstances. If the bladder be healthy, a very small stone may produce trifling and equivocal symptoms. The patient has rather more frequent occasion to micturate; a sense of irritation, scarcely amounting to pain, referred to the neck of the bladder, urethra, and perhaps the hypogastrium, after the bladder has been emptied. In one instance, the patient complained for many months of nothing except an occasional and trifling pain in one of the groins, and of the urine being tinged with blood after riding on horseback. Bloody urine, after any jolting exercise, is a strong indication of a calculus either in the bladder or kidney. But this symptom is often absent in the early stage, while the stone is small, especially if the patient is leading an inactive life. (See *Sir B. Brodie on the Urinary Organs*, p. 225, ed. 2.)

The pain in the groin penis, and even testicles is most severe after drinking water or exercise, when the stone suddenly falls down on the neck of the bladder. This pain "is one of the most marked symptoms of the disease. A child who labours under stone tells you of it, not in words, but in his actions. He is always pulling the end of the penis, and poking it with his fingers, even so as to cause the prepuce to become elongated. You often find his thighs with the cuticle off and swollen, as if they had been soaked in water, from the urine which has been introduced." (*Op. cit.*, p. 223.)

The degree of pain experienced by the patient depends not only on the state of the stone and bladder, but on the size, shape, chemical qualities, and situation of the calculus. "A patient with a single lithic and calculeous suffers less than one with a calculus composed externally of the triple phosphate, and the latter less than one with a mixed calculus. The oxalate of lime, or mallic acid calculus, on the whole, occasions more distress than the lithic and calculeous, probably on account of the irascibility which so frequently exist on the surface of the former; but it occasions less distress than calculeous composed of the phosphates." (See *Sir B. Brodie, Op. cit.*, p. 223.)

According to the same distinguished physician, patients with diseased prostate gland do not generally suffer more from stone in the blad-

der when it affects them, than other individuals, and perhaps less, in consequence of the swelling of the prostate gland hindering the stone from falling on the neck of the bladder. He has, however, seen three cases, in each of which there was a calculus in the bladder; complicated not only with an enlarged, but an increased prostate, and the sufferings were in three instances, terribly severe. In two of them lithotomy was performed; one of the patients died six weeks after the operation, and the other expired immediately comatose, and within a few hours.

OF CUTTING TOWARDS THE SYMPHYSE PUBIS, AND THE BILATERAL OPERATION.

I have already made reference to the plan of dividing both sides of the prostate gland, as practised in 1804 by Dr. Physick, of the United States, and nearly thirty years ago by Sir Assay Crozer, with a beaked double-edged scalpel or a double-edged gorget, in cases where the stone was large, and since occasionally adopted by Sir H. Hughes and others. In 1816, Baron Dupuytren made trial of a method which had, indeed, been suggested at an earlier period by Chamberlain and Riccardi (see *Vigues, Nouv. Essai sur Mict. Calc.*, c. viii, p. 146), which consisted in making the incision into the membranous part of the urethra, as a line with the ridge of the perineum, commencing about two inches and a half in front of the anus, and terminating an inch from it. A second incision, made parallel to the first, divided the exterior penis and the adipose cellular tissue, placed between the bulb of the urethra, in front, and the perineal body. In the third stage of the operation, the membranous portion of the urethra was laid open from the bulb to the membranous. The lithotome, or lancet, curved, was then introduced along the canal, and the latter withdrawn. The edge of the former was then turned upward towards the symphyse pubis, and the blade having been made to cut the sheath by pressing on a spring, the instrument was drawn out in this direction, so as to cut the neck of the bladder and part of its exterior portion, the deepest portion of the upper side of the urethra, the superior part of the prostate, the cellular tissue between the inferior ligaments of the bladder, and the external and crural branches in this situation. (See *Clin. Obs.*, c. vi, p. 374.)

This method was soon abandoned; it had, as the opening was situated in the narrowest part of the arch of the pubes, it must have afforded but little room for the extraction of the calculus. The venous hemorrhage would also be considerable.

In 1824, Baron Dupuytren began to employ his double lithotomes with a steel that had no serrate in any of its edges, which frequently impeded the disengagement of the lithotome from the deep groove of the instrument. The point is placed in the usual position for the lateral operation, and the steel held by an assistant exactly in the vertical direction. While the left hand keeps the arrangements of the perineal urethra, the right makes, with a double-edged knife a semicircular incision, beginning on the right, between the anus and the ischium, and terminating at the corresponding point on the left, the distance to which is passed from the anus forward being five lines. The subcutaneous-cellular tissue, the superficial tissue of the perineum, and the external point of the external sphincter being divided, so as to expose the origin of the membranous part of the urethra, the groove of the

staff can be detected with the nail of the left forefinger, which will serve for guiding the point of the knife into it. During all this first stage of the operation, care must be taken to depress the lower edge of the wound with the finger, and so keep the rectum away from the edge of the knife.

After the membranous part of the sheath has been sufficiently opened, the same finger will serve as a guide for the lithotome, which, held in the right hand with the thumb below and the two fingers next to it above, is applied to the staff with its convexity directed towards the urethra. The contact of the two instruments having been clearly ascertained, the surgeon takes hold of the handle of the staff with his left hand, and, raising its back under the symphysis of the pubis, pushes the double lithotome along its groove into the bladder.

The staff is now to be withdrawn, and the lithotome turned, so as to make its convexity face the urethra. Its blades are then made to girth the sheath, and it is drawn out, not exactly horizontally but with an inclination downward. The left forefinger is then introduced into the wound, so as to ascertain the extent of the incision made, and to guide the forceps to the calculus. (See *Dupuytren, Clin. Chir.*, t. ii., p. 340.)

Bacon Dupuytren ascribed the following advantages to the bilateral operation:

1. The great facility of its performance.
2. The situation of the wound in the widest part of the lower aperture of the pelvis, and consequently the most favourable for the extraction of large calculi.
3. This method makes a shorter and more direct passage into the bladder, whereby the requisite manoeuvring with instruments is facilitated.
4. The readier escape of the urine through the wound, and, consequently, the removal of any risk of its becoming extravasated in the cellular tissue.
5. An opening is made in the neck of the bladder and the prostate sufficient for the extraction of very large calculi, without the wound passing so far on each side as to become dangerous.

6. The evacuator does not encephalic by Dupuytren to be more safe than injury than in the common lateral operation.

7. The method is applicable in both sexes. The bilateral operation has been performed about seventy times in the Hôtel Dieu and other parts of Paris, and only six of the patients died. In that hospital twenty-six patients were operated upon in agreement with complete success. (See *Dupuytren in Clin. Chir.*, t. ii., p. 343.)

The double lithotome is now well constructed in London; and when the stone is known to be of simple case, the bilateral operation, I think, merits the preference to all ordinary plans.

A posthumous work, illustrative of Dupuytren's bilateral operation, and containing several interesting plates, has been recently published.

Mr. Liston is of opinion that no complicated machine is requisite to make this bilateral division, and that it is quite time enough to make such division when the necessity for it has been ascertained. "The single lateral incision affords sufficient room to admit of the removal of the stone in nineteen cases out of twenty, and there can be no purpose served, therefore, in always making a cut in both sides of the gland, and thus endangering the enervation of the individual."

(On *Practical Surgery*, p. 411.) I have already explained that several operations are in the habit of cutting the right side of the prostate gland with a knife when the stone is above a certain size.

TREATMENT AFTER THE OPERATION.

The position in which the patient should be placed after the operation, and the plan of leaving the wound uncovered, so as to let the urine readily escape, I have already described. Professor Jamieson, of Baltimore, who aims at uniting the wound as far as practicable by adhesion, introduces a moderately large flexible catheter through the wound into the bladder, and secures it by a soft strip of rag to the penis. The patient is laid on his side, his knees brought together, and tied by means of a soft silk bandage. No catheters are employed, but the patient must be quietly on his side for two or three days, so as to obtain the effect of a syphon from the tube. "He may, however, after some hours, if particularly desirous, turn upon his left side, yet never forgetting that the outer end of the tube must be lower than the bladder. The patient may be kept comfortably dry by using a cup or large sponge to contain the water as it drops from the tube." (See *Ampr. ed. of the Dict.*) A surgeon at Dundee has lately advocated the same practice.

Sir Benjamin Brodie had the misfortune to lose one testicular hæmorrhage. The case was that of an old man, who had an enlarged prostate and an unusually deep perineum. The blood was venous. If the incision was made low down, and not too extensive, the chance of hæmorrhage seems to Sir B. Brodie to be but small. (See *Dict. of the Theory of Surgery*, p. 298.) In one example under this position, where the size of the calculus made it necessary to cut the right side of the prostate, the hæmorrhage would have proved fatal if an assistant had not pressed the internal pudic artery against the bone with his finger for several hours. In another case, operated upon by Sir E. Home, the bleeding was first suspended by pressure with the finger, and then, as the patient was a thin person, Sir B. Brodie succeeded, with the aid of a small flexible silver needle, in passing a ligature round the trunk of that artery. Dr. Physick, of the United States, once succeeded in tying the internal pudic artery after lithotomy. (See *Ross in Amer. ed. of the Dict.*) Secondary hæmorrhage sometimes occurs after lithotomy, and probably, as Sir B. Brodie suspects, from the separation of a slough. In one such case, Mr. Kele stopped the bleeding by introducing into the bladder, through the wound, a tent of lint, enclosing an elastic gum catheter.

Mr. Key believes that the pudic artery itself is rarely wounded; but that in uniting the artery of the bulb and the superficial perineal branch often bleed profusely. If the incision be made low down in the perineum, he admits that the artery of the bulb may escape; but, from experiments which he has made on the dead subject, he infers that it is almost always divided. He does not approve of plugging the wound with lint or sponge introduced as a catheter. "The cellular membrane is irritated by it, and an unhealthy form of inflammation ensues; while the catheter being some blocked with coagulum, does not carry off the urine from the bladder. I have, however (he adds), found advantage in checking the bleeding by means of pressure made upon the upper part of the left side of the perineum by

a forked piece of lint fixed to a piece of rock-wool in this moderate warmth the deeper branches of the prostate, from which the blood sometimes comes for a long time after the patient is placed in bed, and infiltrate the bladder with masses of coagula." (*See Gay's Hospital Reports*, vol. ii, p. 19.)

I have seen the rectum wounded in three or four instances, but no serious consequences were the result. A wound of the bowel, occurring as it does close to the sphincter, does not appear to Mr. Key to be a matter of serious moment.

I shall conclude this article with the following quotation: "Many individuals (as Sir B. Brodie observes) are good subjects for the operation, and recover, perhaps, without a bad symptom, although the operation may have been very rudely performed. Others may be truly said to be bad subjects, and die even though the operation be performed in the most perfect manner. What is it that constitutes this essential difference between these two classes of cases? It is, according to my experience, the presence or absence of organic disease, especially of the kidneys or bladder." (*Op. cit.*, p. 301.) The enlargement of the prostate gland in old men, I believe with Sir B. Brodie, does not increase the danger, though it may the difficulty of the operation. I infer this from a case which occurred in University College Hospital, and in which the patient recovered without any bad symptoms, though the operation was excessively long, and a portion of the enlarged gland, which had been glyced off, fell down upon the floor.

With respect to stricture in persons, impotency, and sterility of urine, as consequences of lithotomy, I have seen two or three examples of the first. Mr. Key has not witnessed stricture as a consequence of the operation for vesical calculus. "The operation of extracting vesical calculi (he observes) when they are large, and the gland diseased, is sometimes followed by difficulty in passing the external urethra, and the formation of a stricture, through which some drops of urine escape. But in lithotomy, the incision being made through healthy structures, heals quickly by a healthy process of granulation, and finally, is therefore a very uncommon occurrence." Mr. Key has known of one instance in which impotency was ascribed to the operation. But, according to his experience, impotency of some rarely occurs in the adult. "In the young subject, partial incontinence was sometimes occur if the patient is allowed to leave his bed too soon after the operation, before the neck of the bladder is fully healed, and the sphincter has recovered its tone. Instances, therefore, are met with of young boys, who, if they contain their water unconsciously long, and it dribble away as they move about. In bed, the urine is perfectly retained. When they arrive at the age of puberty, the power of retaining it becomes increased." (*See Dr. Key, in Gay's Hospital Reports*, vol. ii, p. 25.)

Lithotomy (from *lithos*, a stone, and *tomia*, I pierce). *Lithotomus* (from *lithos*, and *otomus*, I break). The reduction of a calculus in the bladder into small pieces by means of instruments passed into that organ through the urethra, so that the fragments may be discharged through the latter tube, and no necessity remain for the performance of lithotomy. Although the history of lithotomy goes back to a very old period, the practice of it cannot be said to have been established more than a very few years. The idea of

breaking calculi in pieces was entertained in the days of Alcibiades (*Laus. Times*, p. 94, 1516), but, as my friend M. Leroy of Evreux justly observes, there is no record of the practice having been actually practiced at the period alluded to; and Alexander Benedicinus, of Verona, who published in 1533, mentions the scheme only in speculation. If it be admitted, however, that the Egyptians sometimes broke stones in the bladder, it must be granted that they have left their successors perfectly unimpressed about their method, which stood in need of being revived again. (*See Mém. de la Lithotomie*, Mém. ii, p. 113, 1804, 1805.) The earliest proposal for breaking a stone in the bladder without incision, noticed by Haller (*Med. Chir. Cur. t. i, p. 312*), was made by Santorini. M. Leroy, on referring to the text of this author, believes, however, that it relates, not to the use of any instrument like *la pierre à bras brisée*, with a drill in its centre, but merely to a smaller calculated to extract small stones through the urethra. As for the instrument of Polyzanis (*Medicina*, treating the subject entirely of *Assinus à Crusta*, M. Leroy considers that it can have had no indirect connection with the history of lithotomy, since Polyzanis only employed it for the removal of calculi lodged in the anterior portion of the urethra, and not for the extraction of those of the bladder.

Thus, down to the beginning of the 16th century, no description of any mode of breaking calculi had yet been published. It is alleged, indeed, that successful attempts had sometimes been made before that period by patients on themselves. Thus, a monk of Cîteaux is alleged to have succeeded in breaking a calculus in his bladder by introducing a rod of iron through the urethra, terminating in a chisel, and working it out, or with a hammer. Major Martin (afterwards) his own calculus by means of a file fixed at the end of an iron rod. (*Mém. de Calculus Dissert.*, p. 20, fig. 3.) M. Leroy doubts whether any complete cures were truly thus effected, and refers to some little accounts, by which it appears that Major Martin actually died of stone in the vicinity of Calcutta. Nor does the eminent lithotomist attach much importance to the statement, that Rodriguez, a physician at Mexico in 1600, broke a stone by striking it with a catheter, or, if this were really done, he adds that the success must have been either very small or trifling, and that few could have been thus cured.

Lithotomy was first seriously proposed in 1612, as a method of mechanically breaking stones in the bladder, and then only as an auxiliary to the chemical dissolution of them; the practicability of accomplishing which the writings of Fernelius and Valsartius had raised hopes of. The manner of doing it was suggested by Giraldus, a Bavarian surgeon. His apparatus consisted of a wide, straight tube, through which he passed a noose of copper wire, and a rod ending in a circle of teeth, or a spear point. The calculus was caught hold of and fixed with the wire, and then the circular saw, which was put in motion by means of a lever, was directed to perforate it. The important fact, first demonstrated by Giraldus, is the practicability of introducing straight catheters of large size through the urethra into the bladder, so as to facilitate the necessary measures requisite for the mechanical destruction of calculi.

Some years afterward, Mr. Keilston published in the *Edinb. Med. and Surgical Trans.* for April, 1667, a description of a curved instrument, which

admitted of being opened for the seizure of the stone, and was furnished with a kind of life, that acted by an alternate movement. But the two branches were found insufficient for fixing the calculus, and the bladder was not out of danger of the action of the life. Things had gone thus far when the slight-surgery, with stone bladder and a perforator (le petit à trois branches, à point et à force), were invented in 1823 by M. Civiale, exhibited by him to the Academy of Surgery, and first tried, and this with success upon the living subject by M. Civiale in the following year. In short, after a formal investigation of the merits of the several parties who led the way in these improvements, the Academy of Sciences adjudged one prize to M. Civiale for having first perfected the operation on the living subject; one to M. Leroy for the invention of the process which first succeeded in practice; and another to Baron Heurtefort for the improvements made by him in the operation. (*See Journal Éclairci, De la Lithotomie*, Paris, 1826, p. 114.)

An impartial reader, who reflects upon this history, will perceive, then, that lithotomy has attained the present perfection by the talents and ingenuity of many laborers; and that, while the merits of M. M. Leroy, Civiale, and Baron Heurtefort stand exceedingly high, the originality of the scheme, if not of the practice, is to be traced in ancient writers, and the numerous inventions of Griffiths and Eddison with great be forgotten, though not honored with the praise or commendation of any public body.

It is not my intention in this edition to describe the many instruments proposed for lithotomy, because I know that no account of them would be intelligible without plates, and some of them are no longer used. A clear and excellent description of them, illustrated by woodcuts, has been published by M. Leroy, to which I would particularly refer. (*De la Lithotomie*, &c., 8vo, Paris, 1826.)

The necessity for my entering into the particulars of the very numerous instruments constructed for pulverizing and crushing calculi in the bladder, appears now, indeed, to be needless, because the operation, as first performed on the human subject by M. Civiale with the calicle, three branches, and the drill of M. Leroy, has been nearly superseded by the more simple and expeditious method first executed by Baron Heurtefort. In this improved operation, the patient is placed upon an operation-bed or table which admits of being raised into an oblique plane. At the foot of it is an apparatus which affords a fulcrum to the instrument after its introduction into the bladder. The head of the bed, and, consequently, the fundus of the bladder, may be depressed to any extent desired, the legs which support it being hinged, and capable of folding. On this couch the patient is placed nearly in the position usually chosen for the lateral operation. A strap is passed round the shoulders and buckled to the sides of the table, and the feet are placed in slippers securely fixed at the foot of the bed.

A catheter of the usual length, with a short and rather abrupt curve, is introduced. It serves first as a sound for ascertaining the situation of the calculus, the shortness of the curve facilitating its motion in the bladder. It is furnished with a stovesick. The bladder is next moderately filled with warm water by means of a silver syringe, furnished with a ring on each side of the apparatus by the insertion of two canules, so as to

render the instrument manageable with one hand. The bladder must not be painfully distended with water, because then its action would be arrested, and the fluid would be expelled again. A pair of strong staying forceps, the opposite surfaces of which are furnished with teeth, are then introduced, and the calculus having been seized, the lower piece of the forceps is fixed to a vice at the foot of the bed, serving as a fulcrum, and the upper piece is struck with a hammer, and the calculus broken. Thus neither the shock arising from the concussion is communicated to the bladder, nor is this organ liable to be injured by the fragments being forcibly projected against its internal surface. The instruments are then withdrawn, and the fragments are afterwards washed with the urine. If any fragments remain, capable of being thus discharged, the operation is repeated from time to time, as often as may be necessary.

On the subject of the comparative advantages of lithotomy and lithotomy, it is somewhat difficult to form at present a definitive judgment, because the advocates for one or the other procedure seem to be too much under the influence of prejudice; and in France a degree of animosity has mingled itself with the question, seriously interfering with any just conclusion. When the practice of lithotomy and lithotomy first began, a few years ago, it was extolled as perfectly free from danger, and capable of superseding lithotomy altogether. This representation is incorrect. M. Velpeau declares that lithotomy is generally a longer and more painful business than lithotomy; and that he has known some patients who had been cured for stone by M. Soutterville, after having tried lithotomy under the care of M. Civiale, declare that one sitting for the latter was more painful than all the tedious proceedings in lithotomy. From what I have seen of lithotomy, as practised by Baron Heurtefort, I should say that lithotomy, with some few exceptions, is infinitely less painful than lithotomy; and that many patients, after its performance, follow their common occupations as usual. Two or three years ago the human was killed through, at my request, to exhibit his skill on three patients, in the anatomical theatre of University College, in the presence of all the students and many visitors. The manuvres were executed with surprising precision and quickness. These patients, who had undergone some previous stings, seemed to feel little pain; and, I should say, seemed to exhibit a readiness of the operation with the most cheerful readiness. Still it is not an operation always free from great suffering and danger, and is not applicable to all cases of stone.

According to the researches of M. Velpeau, one third of the patients who undergo lithotomy experience but symptoms, and it sometimes proves fatal, as we are well aware of in Great Britain. Baron Heurtefort has proved that M. Civiale lost 14 patients in 48, and M. Leroy 2 in 98; and M. Velpeau alleges, that an inquiry into the results of lithotomy, in all parts of the world, will not make the average success of lithotomy greater. M. Velpeau adds, that if all the celebrated patients be taken into the account who have undergone lithotomy, and on whom lithotomy might have been practised, the result is still less favorable; for of 20 spoken of by M. Civiale, 31 died within a year after the operation, and 19 did not recover without having experienced severe symptoms. Of 40, M. Leroy only partially cured 22. Of 50, M. Soutterville cured only 22.

upon 2. Henry M. Velpeau infers that at least 1 day out of every 10 or 12 who submit to lithotomy; but that, if a considerable number of individuals, taken promiscuously, were to be subjected either to lithotomy or lithotomy, the average number of deaths would comprise at least one sixth or one eighth of the whole of such individuals.

Yet M. Velpeau admits that, on the whole, lithotomy is a less dangerous operation than lithotomy. On this point I entertain, with him, a well founded opinion as reference to the mere operation. Who can, indeed, get down the manipulations required in lithotomy, according to the best mode of performing it, as generally to be acquired, as referred to danger, with the operation of cutting into the bladder? But this does not settle the question; for, though the operation itself may be infinitely less dangerous, the less radical nature of it, the fragments left behind, and their irritation of the bladder, which is often in a very unfavourable state to bear the continuance of such irritation; the greater chance of relapse, &c. are weighty considerations, which cannot be overlooked. Another fact, very necessary to be remembered in forming a judgment of the merits of the two operations, is, that the individuals most fit for lithotomy are exactly those on whom lithotomy would prove most successful; while those to whom lithotomy is not suitable would have a bad chance of cure from lithotomy. I would not go so far, however, as M. Velpeau, who states that they would have an inferior chance (*Nouv. Elem. de Méd. Opér.*, t. ii., p. 594), because I apprehend that, where the bladder is diseased, or is being affected with chronic inflammation, promptly taking away the stone altogether is better than breaking it, inasmuch as leaving the fragments of it behind, to keep up irritation for a time, must be particularly disadvantageous. Even were lithotomy proved to be decidedly less dangerous in its results than lithotomy, personally speaking, it is certainly not applicable to all cases. It is quite unfit for calculi formed upon extraneous substances, which serve as nuclei; for encysted or adherent calculi; for such as are excessively hard, like some of those composed of oxalate of lime; for calculi above a certain size; for patients whose prostatic, from malformation or disease, will not allow the proper instruments to be introduced. If there be several calculi, an enlarged prostatic gland, or a diseased bladder, M. Velpeau sometimes lithotomy to be at least as dangerous as lithotomy. By general advantage, however, under other circumstances, he seems uncontested, except in children; and, though more liable to be followed by relapse, on account of the fragments sometimes closing the most careful examinations, he gives the preference to lithotomy if two, three, four, five, or even six repetitions of it should be effective. (*See Velpeau, Nouv. Elem. de Méd. Opér.*, t. ii., p. 594.)

Lithotomy, as justified by Henry Henslow, appears to Sir Benjamin Brodie to have several advantages over lithotomy. It is less formidable to the patient. It requires little or no confinement; and many individuals will be induced to submit to it at an early age, who would not hesitate to submit to lithotomy until their sufferings had become excessive, and circumstances arisen to render the operation necessary. This is a point likewise insisted upon by M. Larrey, Mr. Arnott Key (*Gray's Hospital Reports*, vol. vi.), and many other writers on lithotomy. There is no danger of hæmorrhage, nor of those ill consequences which arise from an incision or lacera-

tion extending into the cellular texture around the neck of the bladder. (*On the Use of the Urinary Organ*, p. 346, ed. 2.)

The following appear to Sir B. Brodie to be the principal disadvantages of lithotomy. The patient does not obtain a cure at once; and, in many instances, the process by which the stone is crushed requires to be repeated several times. A small fragment which remains behind will form the nucleus of a new stone, a recurrence of the disease is more likely to take place after the lithotomy operation than after lithotomy, especially in those cases in which, in consequence of an enlargement of the prostate gland, the patient is unable completely to empty his bladder. The operation is only adapted to calculi of moderate size; and, when applied to larger, is either impracticable or difficult, tedious, and painful. When the stone is large, the sharp, irregular fragments lying in the bladder induce inflammation of its lining membrane, attended with severe local suffering, and much disturbance of the general system, either retarding the cure or terminating in death. The complication of disease in the kidney, or bladder, or adjacent prostate, which render lithotomy hazardous, make lithotomy also hazardous. As for the comparative pain, it is so different in different stages of each practice, that it seems difficult to form an opinion on this point. In general, after either of the operations, the patient says that he suffered less than he expected, that is, if the bladder is healthy, and the operation proceeds favourably. If the bladder be diseased, or anything occurs to render the operations difficult and tedious, the patient undoubtedly suffers severely, whether the stone be crushed or extracted by means. Sir B. Brodie then adverts to the sliding fever, shown to him about the year 1804 by Mr. Wain, which were attended to crush calculi in the water by means of the pressure of a screw acted on a hammer; and (says he) as it is now constructed, it seems capable of doing all that can be done with the hammer, unless the calculus be very large, and then the propriety of having recourse to lithotomy in any form is very undoubted. The forceps invented by Mr. Wain are highly deserving of notice, not only on account of their simplicity, but their priority to the pesseros, and some other means for crushing calculi in the bladder. It will be also found convenient, when the stone is small enough to admit of being drawn a certain way into the urethra, and crushed there. For this purpose a pair of sliding forceps may be used, fast without a screw, but to which it may be adapted to the course of the operation. (*See Brodie on the Use of the Urinary Organ*, p. 346.)

Possibility in patients, lithotomy is more difficult of execution than in the adult, in consequence of the tenderness of the works, the immaturity of the parts, and the greater elasticity of the parts. Instruments of more than two lines, or two lines and a half in diameter, cannot be introduced, and, on this account, they cannot possess much strength. (*See Velpeau, Nouv. Elem. de Méd. Opér.*, t. ii., p. 594.) However, that lithotomy is practicable in children under the age of six years is sufficiently proved by some cases recorded by M. Segalas (*Essai Méd. Acad.*, 1824), and by other examples in which that very distinguished lithotomist M. Larrey was the operator. Yet, in one instance under him, a piece of the forceps broke off, which, however, he succeeded in extracting a few days afterwards by means of another forceps. But a

fragment of the calculus now passed into the urethra, and at first could not be pushed back. At length it was reduced into the bladder by Deshayes, who then performed the biphid operation for its extraction. (*Ann. M. Leroy, De la Lithotomie, Mém., 8vo, Paris, 1836, p. 237.*) The reason why cutting into the bladder was then preferred by Deshayes to merely dividing the urethra, by the removal of the stone I do not understand. It is only justice to my friend M. Leroy to state, that he carefully admits that for children lithotomy should not be preferred to lithotomy, unless the calculus be known to be of small size. In them lithotomy is attended with little risk of dangerous bleeding, effusion of urine, peritonitis, or cystitis, and the operation is completed in a very short time. In infancy, among other considerations against lithotomy are, first, the high situation of the bladder in the pelvis, which greatly increases the curvature of the posterior third of the urethra; and, secondly, the increasing elements of success from lithotomy at this tender period of life. For a corroboration of the doctrine that lithotomy is preferable for children, I refer also to the arguments of Mr. Austin Key. (*See Gay's Hospital Reports, vol. ii.*) One of the gentleman's arguments is, that lithotomy should be generally preferred in children and elderly subjects.

In some persons, the condition of the prostate gland pushes the urethra up behind the symphysis pubis, and renders lithotomy very difficult. For obviating this impediment, H. Leroy invented a contrivance (*hydrostat de Pambou*) for rendering the passage straighter. It consists of an elastic gum catheter, which is first introduced curved, and then straightened by means of a rod (mandrin), which is slowly propelled into it from before backward with a screw. But, as M. Velpeau observes, there is danger of confining the verumontanum with this instrument, or of lacerating the posterior side of the urethra. Another instrument of this kind, invented by M. Tanchou, seems to M. Velpeau safer, as the third of it to which the bladder consists of little pieces articulated together, so that the instrument admits of being first introduced curved, and then straightened. (*Nouv. Rev. de Méd. Opér., t. iii. p. 304.*) But, now that the breaking of calculi in the bladder is usually effected with the sliding forceps, acted upon by a screw or the hammer, and such instrument is necessarily curved, these contrivances for facilitating the introduction of straight instruments are of less importance than they were a few years ago.

Among the occasional or consequences of lithotomy, that severity of the pain is sometimes dwelt upon, therefore I have already stated, the pain complained of varies in different individuals; he reasons already hinted at. Until lately, much of the pain frequently depended upon the action of straight instruments, which hardly scratched the vesicular portion of the urethra; and, as M. Velpeau remarks, the use of curved instruments will prevent this cause of suffering.

In some cases, each application of lithotomy is followed by a paroxysm of fever. It is an accident that may follow the most simple use of a catheter or bougie; it often renders it necessary to remove the intervals between the operations at the operation. In many cases, the serous coat and muscle swell, owing to the contusions and abrasions of the verumontanum, and terminations of the ureters, vesical extravasation, and

decreases in the peritonæum and scrotum, have also been occasionally noticed. I know of one case myself, in which the patient died of effusion of urine.

In some instances, cystitis, proctitis, and fatal nervous disorder arise from injury of the bladder with the forceps, or the irritation caused by the sharp angular fragments. I know of two or three instances in which the patients were seized with violent visceral spasms directly after the operation, and expired in the course of a very short space of time after their removal from the table. In other cases, excruciating of urine, or paralysis of the bladder, has ensued. In many instances, the fragments enter the urethra, and cause retention of urine, accompanied by severe suffering.

M. Blandin witnessed an instance in which the bladder was perforated, and I have heard of a similar accident in London; though, as M. Velpeau justly observes, such an occurrence ought to be exceedingly rare with a circumspect operator.

The passing of the bladder, another accident, may, in general, be avoided with tolerable certainty by not suddenly closing the lithotripter until the calculus has been felt to be grasped by it, and the instrument has been kept drawn a little way towards the vesical orifice of the bladder. The last accident, and not the least serious, to which lithotomy is liable, is the breaking of the instrument in the bladder, or with a bending of it that it cannot be withdrawn through the urethra. In the first case, lithotomy becomes indispensable; in the second, it may become necessary to cut down to the instrument in the peritonæum, and draw it with a file, before it will admit of removal. I know of instances in which such things have been accomplished.—C.

[Lithotomy has already excited the admiration and rivalry of many of the transcendental surgeons, and has been often successfully employed in the United States, where it is regarded as, in certain cases, of course, greatly to be preferred before lithotomy.]

Among those who have been emancipated with the new operation, and have done much towards introducing this improvement into the United States, Professor Gross, of Philadelphia, deserves honorable mention. This eminent surgeon has always contended that lithotomy is a difficult operation, requiring great dexterity, a perfect familiarity with the use and knowledge of the mechanism of the complicated instruments, and, without a full supply of the instruments adapted to so many purposes, and hence within the reach of but few surgeons. He has therefore protested against the notion that "lithotomy is so very easy and simple that it may be performed successfully by those who would not dare to venture on lithotomy." The frequent failures of surgeons both in Europe and America, have served to fortify his opinions, and confirm the propriety of his judgment, for even in the hands of Dr. Phœnix lithotomy has been followed by disastrous results. At the same time, Dr. Gibson does not overvalue the merits of this brilliant discovery, and he awards no undue extraordinary skill, tact, and success in the part of his own instruments in which he excels, however, he has few equals; but he insists that for success very good skill is demanded in the operation, very perfect instruments in regard to their construction and temper, but, above all, most accurate discrimination as to the cases to which it is adapted.

But lithotomy he regards as within the reach of a much greater number of surgeons, less painful to the patient, attended with little or no risk, if suitable care be used in selecting the cases and in employing the instruments; provided the patient will submit to the necessary restrictions; and he thinks, under favorable circumstances, it is certain of success.

Lithotomy proposes two objects, viz., crushing and percussion. The former of these processes is adapted to both soft and brittle stones; the latter to those which are hard and compact. Several instruments have been invented for this operation, but the two most generally preferred are those of Simon Heurteley and M. Jacobson. For an accurate description of these instruments, and a critical examination of the merits of each, reference may be had to Dr. Gibson's Institutes of Surgery, last edition, which is illustrated by very accurate drawings, which it is impracticable to give here. Preference is here given to the instrument of Heurteley, for reasons which are assigned at length. When the stone is small and has not existed very long, and if the patient be an adult having in other respects a sound constitution, and the bladder and ureters be not remarkably irritable, lithotomy may be performed with every probability of success, and in such cases should be preferred to lithotomy or lithotrity; but, on the contrary, in the absence of these favorable conditions, and especially under an opposite state of things, especially if the stone be large, hard, and rough, and the constitution have greatly suffered, the chances of recovery would be greater by lithotrity. Especially in children, no operation other than lithotomy should be attempted, and happily, in such cases, there is little to fear from the lateral operation, as the almost uniform success attending it on boys amply shows. The operation of lithotrity, however, is adapted to those frequent cases of adults and aged people who suffer from stone, while the constitution has not yet essentially suffered, nor the bladder become diseased, nor has the stone acquired a large size. The pain and danger being inconsiderable, such persons, on being informed of the advantages of lithotrity, might be induced to submit to it early, instead of delaying, as they are wont to do, until so late a period that but little chance remains of success by either operation.

For lithotrity, Dr. Gibson regards a preparation of the patient necessary by strict diet and depletion, unless it be contraindicated. He thinks it important that very low diet, with occasional laxatives, should be ordered, for weeks in some cases, as preliminary to attempting lithotrity. A very minute account of the successive steps in the operation will be found in his work already referred to, and our limits will only allow of a brief reference to his cases, which may be found in the American Journal of Medical Sciences for 1827. It will be there seen that Dr. Gibson has reported five cases, in three of which he was completely successful by a repetition of the operation of lithotrity; and in one of which he succeeded but partially, owing to the long exposure of the disease and his lithic diathesis. With a candour which, however worthy of imitation, is rarely exhibited, he gives the details of a fatal result of one operation, which he ascribes in part, and not without reason, to the ungovernable habits of the patient in regard to indulging his appetite. In all these cases he used Heurteley's instrument, though in one of them

he had previously tried that of Jacobson, at the instance of the patient, who preferred it, and, by the suffering it inflicted, he gave up his preference, and then experienced the advantages of the other, by which he was completely cured.

Dr. Randolph, of Philadelphia, and Prof. Nathan R. Smith, of Baltimore, have been successful in the use of Jacobson's instrument, although both their surgeons have since adopted Heurteley's, and now prefer it as performing lithotrity.

I have only room to add, that after summarizing his objections to the instruments of Jacobson, while, nevertheless, admitting its several points of merit and admirable ingenuity, Dr. Gibson gives the following reasons for his decided preference to that of Heurteley. 1st, In addition to its working upon the principle of crushing, percussion, it combines the important power of compression; 2d, It does not give so much pain either in introducing it or in operating it in the bladder; 3d, It can grasp a larger stone; 4th, Its hook can descend behind the prostate, and enter every corner or pocket of the bladder; 5th, It is extremely well adapted to seek out and pick up fragments; 6th, It is impossible to push the bladder where the surgeon craves it to do it; 7th, It might be used to good purpose, when well tempered, to break it, though Jacobson's chain is possibly still stronger; 8th, The facility of the groove in the female and its becoming lodged with small and small fragments, so as to give the patient pain in withdrawing the instrument, is obviated by a little practice, by moving the handle, and by slight lateral movements, washing out the fragments, and afterward crushing the remainder by a few taps of the handle. The stone window lately introduced at the extremity of the instrument, moreover, completely overcomes this difficulty.

It is but just to add, that there are some surgeons who still give the preference to the other instrument. Dr. Norris, in his last edition of *Lithon.* says, "The 'stone press' simply of Jacobson is the instrument generally used and so of this country. It combines great power of action with delicacy of form and structure; and it is by accident it should be broken, in cases in which I am not aware of even having happened, it may be withdrawn without that difficulty which has occurred with the instrument of Heurteley. Besides, it may serve as well a stone as the other, is not so liable to catch the bladder, catches more easily, and holds fairly the calculus when introduced."

In England, both these instruments have been succeeded by the recent invention of Mr. Wilson, a graphic description of which will be found in Dr. Fane's *Obstetrics of Bristol*, lately published, as also in Dr. Norris's edition of *Lithon.*

Dr. J. C. Warren has performed the lateral operation of lithotomy 18 times, and succeeded in all but two. He has only associated lithotomy once, and then with complete success.

Dr. Owen, of Charleston, divided both lobes of the prostate in lithotomy some years since, and Dr. Eys, of Georgia, did so too. Successive, using DePuy's double lithotome rather, and he treated a large stone of the maternal organ. In one of Dr. Warren's cases, lately reported in the New York *Lancet*, both lobes of the prostate were divided.

Professor Dudley, of Kentucky, has performed excellent, both in the number and success of his operations, any other surgeon in America, has

ing, as early as 1838, performed the lateral operation of lithotomy 170 times, and only one of these failed to recover by the evacuation or aggravation of other diseases. His extraordinary success has been attributed to his careful selection of cases upon which to operate, which, if true, as alleged, is highly complimentary to his discrimination and discretion; while others ascribe it to the preparation to which he subjects his patients prior to the operation, and which, it seems, consists mainly in restoring the digestive organs by suitable medication, another evidence of his science and skill.

In Dr. Bush's able paper on the subject, published in the *Transylvania Journal*, however, it will be seen that, though Professor Dudley does not claim any novelty in his operations, yet there are peculiarities, nevertheless, which entitle him, by comparison with other surgeons, to the merit of novelty. Alas! that my limits will not allow me even to indicate the features of his operation, which I regard as ingenious, new is it necessary to vindicate the claims to which his unparalleled success entitles him, as to this operation pre-empted among surgeons. I only regret that my failure to hear from him has deprived me of the ability to do him justice, by recording his skill in other departments of operative surgery to the extent he deserves.

By Dr. Flint's edition of *Desault*, lately published, it appears that Dr. Dudley invariably uses the gorget for the prostatic section; and in employing this instrument, he is almost alone in America, and yet his astonishing success might be urged as an argument in its favor. Most American surgeons, instead of the gorget, employ either the bistoury or Mr. Leitch's domestic scalpel, with a cutting edge, extending from the point to about midway of the blade; and Dr. Flint employs the latter instrument for all his sections in lithotomy, from the subincision through to the bladder. A valuable paper on the nature and treatment of calculus disorders, in review of Dr. Dudley's pamphlet, may be found in the *Amer. Journ.* for 1851.

Dr. Allen Giddens, of New-York, has performed the lateral operation of lithotomy 38 times, and has been successful in all but three; and the failure in those were attributable to complicated disease and advanced age, the cases being most unpromising. Dr. Giddens has performed lithotomy three times, and lithotomy six times, with favorable success. Three of these cases were children.

Dr. Mutter prefers a grooved staff, very slightly curved, in the operation of lithotomy, and uses a common scalpel for all the incisions. He has had great success in the treatment of stone, both by cutting and trussing. For this last purpose he prefers Jacobson's instrument.

The merit of being the first in the United States to perform the operation of lithotomy is due to Dr. Doyere, of New-York, and the successful case is reported in the *New-York Med. Journ.* for February, 1831. He employed the instrument of Civiale, and pronounced his method, Dr. J. Randolph, of Philadelphia, in the year 1834 reported six successful cases of lithotomy by Baron Heurleberg's method, in conjunction with the plan of Civiale, so that Dr. Randolph was the first in America to succeed with lithotomy. In 1836 he reports in the same journal seven additional cases, and in 1837, four more, all successful.

Dr. C. W. McCluskey, of Philadelphia, has

now performed the high operation for lithotomy nine times, and the lateral operation twenty-one times, with uniform success, five of the latter being females. He has reported lithotomy thirteen times, and has only failed in one case. Dr. J. Rhca Barton, of Philadelphia, has several times used lithotomy, but he thinks there are but few cases of stone to which it is adapted, and that but few surgeons will ever expect to this method, because of the fact it demands, and which can only be acquired by long experience and frequent operations, such as rarely fall to the lot of any individual in this country. Dr. J. Randolph, of Philadelphia, was among the first in this country to cultivate the arts of lithotomy and lithotomy, and has been more successful than any other surgeon in the United States, both in adults and children.

Dr. J. Rhca Barton has performed the lateral operation of lithotomy thirty-six times, of which he has lost four patients, all of which were unpromising cases, in their previous aspect, but the operation adorning, nevertheless, the only chance of giving possible relief, three of the patients being of very advanced age, and worn out by the long continuance of the disease.

Dr. Nathan R. Smith, of Baltimore, has operated in forty-five cases demanding the lateral operation for lithotomy, of which he has lost but three. He has also treated eleven cases of stone in the bladder by lithotomy, in all of which he has been completely successful, except in one very unfavorable case, in which no form of surgery offered any hope of success. This eminent surgeon has applied his extraordinary mechanical genius to the improvement of the instruments used in lithotomy, and with a success which has deemed this formidable operation of but its terrors to the surgeon, and greatly diminished its dangers to the patient, having constructed a staff and a knife, both of which are of great practical value.

Dr. N. R. Smith has succeeded with lithotomy in five male children, one of whom was but one year and ten months old, which is the youngest child upon whom it has ever been performed. Dr. Randolph, of Philadelphia, was successful with the same operation in a little girl of four years of age, and a boy of thirteen.

Dr. Mott, of New-York, has performed the lateral operation of lithotomy in a great number of cases, and during an extensive practice of thirty-six years, has lost but four of his patients. He exclusively employs the bistoury for the prostatic incision, and is wont to say in his lectures that he has never used a gorget on a living subject.

Dr. Parker, of New-York, has lately performed the high operation of lithotomy on an adult female with complete success. He was led to this method by the very large size of the stone, which forbade the hope of its extraction by Lisfranc's method of enlarging the urethra, and preferring, as he very properly did in such a case, the high operation to the vaginal-vesical incision.

Dr. Mutter, of Philadelphia, reports, in the *Amer. Journ.* for 1847, a case of urinary calculus extracted from a girl of nine years old, by enlarging the urethra, the incision being made with a bistoury upward towards the pubis on a grooved staff, on the plan of Dubois, and which was attended with entire success. Dr. J. Rhca Barton, of the same city, has also practiced this method with the like result, and in neither of these cases did any degree of inflammation of urine follow.

On this subject Mr. Cooper says, "Turner on

four years ago I assisted Mr. Wain, of Bloombury Square, in extracting a calculus which was nearly an inch and a half in one of its diameters, from the bladder of a girl eight or ten years old. The meatus was first gradually dilated with Weiss's dilator: the incision of urine, following the opening, after a time subsided. I have also seen a piece of spermatocæstic, five inches long, and of the usual thickness, which had accidentally slipped into the bladder, taken out with the finger, after the meatus had been dilated for two or three hours with the same instrument; and in this case no inconvenience of urine followed."

Dr. J. K. Rogers operated on a female, and extracted a stone weighing 5 oz. and 5 drachms, with complete success by a lateral incision, enlarging the urethra until it could be extracted. This is the largest ever extracted with success from the human bladder, and the patient recovered without inconvenience of urine, in any other untoward symptom. Dr. Mott extracted a stone weighing 17 oz., which is the largest on record, but the patient failed to recover. (Excerpt.)

LITHOTOMY BY THE RECTUM. Performed by Mr. Dawson, of the Liverpool Infirmary, on a little boy of three years and a half old. The case, a sacculated calculus, hanging downward, so as to be felt through the upper wall of the rectum. "A pain-bonnet, having its anterior edge rounded and very keen, was laid flat on the finger, which, thus armed and aided, was introduced through the anal opening to reach a point a short distance beyond the recto-vesical pouch, when its edge was turned upward, and a decided cut made by drawing the instrument from behind forward in the median line, through the walls of the pouch, and up to the stone, on the hard surface of which the edge of the finger was distinctly felt to grate." After a second cut, the calculus was displaced by the finger, and fell into the rectum, where it was withdrawn with Pezzer's double-screw wire. For four days urine was discharged from the rectum. On the tenth day, four ounces of urine passed in a full stream through the penis, and after this no urine was voided from the rectum. The child recovered favourably from the operation. (See *Transactions of Med. and Surgical Provincial Association*, vol. II, p. 301. To the references at the end of the article in *Lithotomy*, add *The Surgical Anatomy of the Perineum*, by Thomas Morton, late House Surgeon in the University College Hospital, 8vo, Lond., 1828.)—45.]

[LOWER JAW, EXCISION OF THE EXTREME.] (Case by John G. Perry. The disease necrotic, with several abscesses arising around the alveoli.) One of these having burst had open, the entire base of jaw bone was found to be dead, and in a great measure separated from the surrounding tissue. The removal of this bone was therefore determined upon. An incision was made along the base of the jaw, from a short distance in front of the right masseter muscle to the corresponding point on the left side. The exposed bone was covered with a raw and shining fungus, as seen on incision in the angle of the jaw, and the necrotic portion removed. On the following day the portion remaining in the right side, which looked somewhat discoloured from the loss of the support of the costal part, was removed, without difficulty. At the end of three weeks the remaining segment was taken away. After a month, the patient was able to masticate food with the aid of the tongue, which now

the moved against the upper teeth; but, as there is no reproduction of bone, the lower teeth are almost useless, and they do not meet the upper. (See *Med. Clin. Trans.*, vol. XX, art. II.)—46.]

[LUMBAR ABSCESS.] The symptoms are commonly of the following kind: pain in the lumbar region, shooting to the groin and thigh, and stiffness and pain in the course of the spine, which symptoms are exacerbated by extension of the thigh. The patient cannot stand well on the feet, and either limps in walking, or cannot walk without stooping. Any effort causes an increase of pain. Sometimes the inguinal glands are enlarged. According to Dr. Kell, of Wexford, the disease admits of being discriminated from others, even in the earliest stage, by the following circumstances: the patient cannot walk in the upright position; he always leans a little forward; he can only straighten himself to a certain point, and he is stopped by a burning pain, which is felt at the same point in the groin and knee. The patient can go up stairs more easily than he can come down, because, in the latter movement, he is obliged to hold himself up. These symptoms are usually prolonged for several weeks, or even months, by dull pain in the lumbar region.

Lumbar abscess may be mistaken for inflammation, affections of the kidney, conical, lumbar, herpetic neuralgia, pleuritic swellings, and leucost. I have shown the latter mistake recently made when the abscess had formed a small opening below Poupart's ligament. The points of difference are noticed in the article *HERPES*.

I have attended several patients, each of whom had a double lumbar abscess. Two such cases were lately under me in University College Hospital, and ultimately recovered. In the case hospital we have seen patients whose legs were drawn into complete contact with the body from the effects of lumbar abscess; yet after the discharge of the matter, the limbs gradually resumed their proper position and use. The lumbar abscess is sometimes attended with diseased vertebrae, which may either be a cause or an effect of the collection of matter. The disease, however, is frequently attended with this complication.

Chronic abscesses perpetually form in the lumbar without vertebral disease, and not well with ordinary care. (*Moys, Outlines of Human Pathology*, p. 124.)

The practice of opening abscesses connected with the larger joints is considered by Dr. M'Donell to be, in general, decidedly injudicious; but, says he, "when we consider the fatal consequences which may result from the unchecked progress of the deep abscesses, and take into the account the very great sufferings of the patient from pressure of the anterior crural nerve and its filaments, I believe this to be a case in which surgical interference is called for. The opening of this abscess, however, requires much caution. In superficial purulent collections in the lower part of the perineum, the abscess is detached, and pushed up, ward and inward sufficiently to permit the insertion above Poupart's ligament being made with perfect safety; and so in the deep collections, there is then no separation of the perineum, and the opening must be made below Poupart's ligament, and of course, with great caution." (See *M'Donell, in Dublin Journ. of Med. Science*, vol. IV, p. 12.) See also Cooper's *System* respecting the practice of opening abscesses connected with large joints, I have noticed in the article *JOINTS, DISSECTIONS OF*.—47.]

M.

[**MELANOSIS**, derived from $\mu\kappa\alpha$, black, is a term employed to signify substances, occasionally developed in or upon the tissues of the animal body, and characterized by their black colour.

Although references to melanosis of the lungs and liver may be traced in the writings of Boerhaave, Morgagni, and Haller, the first very careful descriptions of the disease were given by MM. Dupuytren, Bayle, and Larrey. The name of melanosis, which was first adopted by Larrey, who published the earliest particular account of the disease (*see Bulletin de la Soc. de Médecine de Paris*, 1806 No. 2), is still generally retained. Professor Carswell uses the term *melanosis*. Our knowledge of the disease has been of late years much extended by the speculations of Breschet, Tromsøen, Leblanc, Canstatt, and some eminent veterinary surgeons in France.

Under the title of *melanosis*, Dr. Carswell includes all melanotic formations, black discolorations, or products, described by Larrey and other authors; but, for the purpose of marking the difference in their nature, he arranges them in two groups; the first being distinguished by the appellation of *true melanosis*; the second by that of *spurious melanosis*. "Thus, (says he,) when these formations or products depend (as is the case with some of them) on a change taking place in that product of secretion, whence the natural colour of certain parts of the body is derived, or, in other words, when they constitute what is called an *idiopathic disease*, I shall consider them as belonging to the first group; and when, as is the case with others, (they originate in the accumulation of a carbonaceous substance introduced into the body from without, the action of chemical agents on the blood, or the stagnation of this fluid,) I shall include them in the second group. There are several black discolorations, which might also have been included in the present systematic arrangement, such as those observed in tissues affected with mortification, that have been subjected to the action of intense heat, or powerful excretories of various kinds; but as they have previously confounded with any of the forms of melanosis, I shall not take any farther notice of them in this place." Dr. Carswell then proceeds to describe, 1. *True melanosis*, of which there is only one kind. 2. *Spurious melanosis*, of which there are three kinds:—1. From the introduction of carbonaceous matter. 2. From the action of chemical agents on the blood. 3. From stagnation of the blood. (*See Illustrations of the Elementary Forms of Disease, Part, on Melanosis*.) According to Dr. Carswell's definition, *true melanosis consists in the formation of a solid, organized product of secretion of a deep brown or black colour, and the form and consistence of which present considerable variety, solely in consequence of the influence of external agents.*

Melanosis is more frequently observed in the cellular tissue than any other, and perhaps it is in consequence of that tissue entering into all the vascular structures and organs of the body, that melanosis is sometimes noticed in most of them. Thus, Audouin describes examples of melanotic fontanels in a great number of the ele-

mentary tissues, where it may either exist singly, or in thien with other tegular disease. (*See Précis d'Anat. Pathol.*, t. i. p. 408.) Melanotic productions may also be met with simultaneously in various textures and organs. M. Martin relates the case of a woman, in whose right inguinal glands, bladder, and testis, melanotic tumours had formed. (*See Archives Méd. et Chir. Progrès*, t. vi.) M. Albert gives another case, where the skin, the great vessels of the cellular tissue, the mediastinum, the mesentery, omentum, many lymphatic glands, the thyroid gland, and the lungs, all contained melanotic deposits.

In the cellular tissue, the most frequent seat of true melanosis, the melanotic matter is formed after the manner of secretion, accumulates in the cells of that structure, and gradually assumes the form of tumours of various sizes. A similar mode of formation is still more conspicuous in loose cellular tissue, and particularly on the surfaces of serous membranes, like those of the pleura and peritoneum.

The next variety, noticed by Professor Carswell in the seat and mode of formation of melanotic matter, is that of its deposits in the substance or subcellular structure of organs, after the manner of nutrition. Lastly, he adverts to the detection of melanotic matter in the blood, chiefly that contained in the venous capillaries, and under circumstances which prove, that it must have been formed in these vessels. (*See Illustrations of the Elem. Forms of Dis. Part, on Melanosis*.)

There are four varieties of true melanosis. (*See Abstract, Précis d'Anat. Pathol.*, t. i. p. 448.) The following names have been applied to them:—

1. The *melaniform* (melanotic infiltrate) is that in which the melanotic matter presents itself in minute points or dots in the texture of an organ; it is principally noticed in the lungs and liver.

2. *Tuberiform melanosis* (concretions melanotiques, inclusiones in matter) is the most common variety of it, and is occasionally met with in most of the organs of the body, and sometimes on the surfaces of serous membranes. "In the former situation" (says Dr. Carswell) the tumours are generally globular, and in the latter not infrequently pyramidal. They are most frequently found single in organs, and aggregated to cellulae and adipose tissue, and liver, perhaps, except liver found limited to one organ, the deposition of the melanotic matter taking place simultaneously or successively in a great many organs, or in the cellular tissue of the different regions of the body. "The melanotic tumours are most numerous in the cellulae and adipose tissues, but from their aggregated position lobular or irregularly shaped masses of great bulk." Melanotic tumours are sometimes bounded by cysts, but more frequently have no cysts. (*See Abstract, Précis d'Anat. Pathol.*, t. i. p. 451.) but are in immediate contact with the texture in which they are produced. Larrey, indeed, divided melanosis into the *crystalline*, and *non-crystalline*. According to the researches of Dr. Carswell, melanosis is perhaps never found encysted in compound tissues, or organs, as the brain, lungs, liver, and kidneys; whereas it is always so in

the cellular and adipous tissues, and sometimes on the surface of serous membranes.

3. *Stratiform melanosis* (*melanose membraneuse*) is represented by Dr. Carswell to be formed only on free surfaces, though M. Blaud states, that it is occasionally produced on the adherent surfaces of serous membranes. As the name leads us to understand, the melanotic matter is deposited in the form of strata, or layers, or of a pseudo-membrane. Its existence generally resembles that of jelly, and is enclosed either in a soft spongy cellular tissue, or fine transparent serous membrane of new formation, so that, when pressed, it feels jelly, but is not removed by the finger, or a surgical probe over it, unless some force is employed.

4. *Liquiform, or fluid melanosis*, was not described by Laennec, which, as Andral remarked, is not surprising, inasmuch as he regarded melanosis as a tissue or texture. M. Brocchi has applied this name to certain liquids of a dark colour, which seemed to him to arise from morbid secretion. In some individuals, M. Andral found in the cavity of the abdomen, after chronic peritonitis, a black fluid which he regards as liquiform melanosis. Dr. Carswell remarks, that "the appearance of true melanosis in a liquid form has in general been confined to natural or accidental serous cavities. Among the latter, the cavities of the pleura and peritoneum furnish almost the only examples in which the liquid melanotic matter has been observed, and that too in very small quantity. I have never seen it in man as a product of secretion, but have met with it in consequence of the destruction of melanotic tumours, and the effusion of their contents into serous cavities, the walls of which they had perforated. The accidental serous cavities, in which it has been found, are those which constitute cysts, particularly in the ovaries." MM. Trousseau and Le Blanc met with a fibrous cyst, as large as the fist, situated above the kidneys of a horse, and containing about eight ounces of black liquid.

Brocchi, Andral, and Carswell, in describing liquiform melanosis on mucous surfaces, especially that of the stomach, have confounded it with the black discoloration of effused blood, produced by the action of the gastric juice upon it. (Carswell.)

The largest melanotic masses are found in the loose cellular tissue behind the peritoneum, and these are always composed of many smaller ones. The largest single tumours are noticed in the liver. In the horse, masses of true melanosis have been found in the former situation, weighing from twenty to forty pounds. (Id.) It is further explained by Dr. Carswell, that the consistency of true melanosis is determined by the texture and form of the part in which it is deposited. "Thus, it is never found solid in serous cavities; for the plasma tumours, that its diffusion is not limited by dense surrounding tissues. Even in tumours attached to the serous covering of these cavities, it is for the same reason either perfectly fluid, or not more dense than animal jelly. Loose cellular tissue (also pervasively filled with the black matter) is a fluid state. In the dense texture of the ovary, on the contrary, even the smallest tumours may be as hard as cartilage, and are generally as firm as the pancreas. In the lymphatic glands, and in the brain, the melanotic tumour acquires only a medium degree of consistency, although it is generally softer in the former than in the latter, in

consequence of the capsule of the glands acting as a compressing cause.

Melanotic tumours are susceptible of a softening process, especially when situated near the surface. The skin becomes thin, atrophied, and a fleshy blackish matter, characterizing the disease, is discharged. This is what M. Blaud saw take place in an old woman, who was afterwards admitted into La Salpêtrière, and whose case is recorded by M. Brocchi. (See *Mémoires de Javon, de Physiologie Expérimentale*, t. i. p. 264.)

Melanotic tumours, attacked by absorption, or the knife, pour out blood as well as a blackish fluid. They may also throw out granulations, suppuration and heal, as was exemplified in the horse operated upon by M. Dumas, the particulars of which were published by M. Trousseau. (*Archives*, June, 1828, p. 120.) In ordinary cases, melanosis is not productive of much disorder in the economy. In the liver and the cellular tissue of many organs an excessive magnitude without growing rare, during life, is the slightest functional disturbance leading to the suspicion of its existence, pointed it does not cause any mechanical oppression. When melanotic tumours exhibit any inflammatory action, or disposition to hemorrhage, it is the cellular tissue in their structure that is the seat of these changes, just as it is the seat of cancer which sometimes invades melanotic tumours. (Blaud, in *Dictionnaire de Médecine et de Chirurgie*, t. xii. p. 264.)

Dr. Carswell and M. Andral differ from Laennec in believing the melanotic matter to be deposited first in a fluid state, and afterwards to acquire greater consistency from the cellular tissue in which it becomes developed. At an indefinite period of its formation, however, Dr. Carswell admits that the solid melanotic tumour loses its consistency, and softens; yet this change does not appear to him (as to M. Andral, as it did to Laennec, (*Précis d'Anat. Pathol.*, t. i. p. 450.) to be a vital process, originating in the melanotic matter itself, but to depend upon the destruction of tissue, which occurs, or are contained in, the melanotic tumour, and upon the simultaneous effusion of serosity. Inflammation rarely accompanies the softening process, and, when absorption and sloughing occur, they appear to be chiefly owing to the melanotic matter compressing or obliterating the blood-vessels of the tissue in which it is contained. (Carswell, *Op. cit.*)

The texture of the melanotic matter is homogeneous, void of small vessels, and a fluid exudes from it, which stains the fingers black; and it is not itself organized. In vain (says M. Andral) should we look for any trace of organization. It is merely a homogeneous substance, sometimes divided into blades, or layers, by cellular tissue, which pervades it, without belonging to it. There are neither cavities, vessels, nor fibres in it: no vessel, no nerve, is distributed in it. No characters exist entitling it to be called a texture.

As Professor Carswell observes, "when a number of melanotic tumours are grouped together, they are included in a common capsule, and separated from one another by their respective coverings and portions of cellular tissue, contained in the angular spaces sometimes left between them. It is in these situations and cellular tissues alone, that blood-vessels or nerves are to be seen. Minute arteries and veins may be observed ramifying in both, but they never pass beyond the limits of these tumours.

Large branches, and even trunks of arteries and veins are sometimes found passing over the surface, or included in the aggregated masses of melanotic matter." (See Cuvier's *Elém. d'Anat. de l'Homme*.)

With respect to the chemical composition of melanosis, M. Thénard detected carbon in it; M. Clapton, albumen and a peculiar black colouring matter; and M. Baurd accertained, that this last is analogous to the colouring matter of the blood. He also made out the presence of a particular modification of albumen in it, and the existence of phosphate of iron in it; elementary ingredients also in the blood. M. Bury made a comparative analysis of saccharine or emphyreolized, scirrhous, and melanotic formations, and he detected in these different substances albumen, fibrine, and some of the bases of which were soda, potassa, lime, and oxide of iron, in rather less proportion in the two first formations than in melanosis; and in this latter a highly carbonized principle, composing nearly one third of it. These various researches thus all tend to prove a close analogy between the elements of melanosis and those of the blood.

Melanosis is not restricted to man. It is more frequently noticed in white and gray horses than in those of any other colour. M. Ridel and Brochard have met with it also in bones of a light bay colour; and dogs, cats, rabbits, mice, and rats, are all subject to it. In horses, melanotic swellings form especially under the tail, and thence extend in greater or lesser distance within the pelvis. They may often be removed from this situation with success.

Though melanosis may occur at any period of life, and even in the foetus, a melanotic formation on the corneal film exemplified in a preparation in University College Museum would tend to prove, yet it is more common in adults and aged persons than very young individuals.

Melanosis was regarded by Linnæus as a species of cancer. (*Diagnos.*, t. ii. p. 33.) But in its appearance and progress, it is very different from the latter. The white resplendent hair and the lustrous texture of scirrhus, which yields a grating noise as the knife passes through it, present no resemblance to melanosis. The tumefaction pains of cancer; the characters of the emphyreolized tumour; the tendency of these formations to be reproduced after having been destroyed; the hectic fever and other derangements of the health to which they give rise; are circumstances sufficiently marking the difference between melanosis and cancer. The only examples, like by to have occasional such mistake, are those in which melanosis and cancer are united together. The same remark applies to tubercular disease. The cancer scirrhus of Alibert, and the cancer aneurysm of Junin, seem to have differed from simple melanosis in their tendency to be reproduced in other parts after extirpation, and in their disposition to soften and be accompanied by ulceration, and all the evils peculiar to cancerous diseases. At all events, then, it would seem as if there are modifications of melanosis, which are of malignant character, whether we adopt the doctrine or not, that they are combinations of cancer and melanosis together.

The fact of melanosis taking place chiefly in white, gray, or light bay horses, is a curious one, seeming to prove that the black matter of the accidental production is deposited in internal organs, as it were, in consequence of such colour-

ing matter not being secreted by the skin. Perhaps, however, as M. Andral observes, there has been too much disposition to generalize on this point; for M. Ridel has published instances of melanosis in horses of all colours. (See *Ann. Pathol.*, t. i. p. 475; and *Ridel, in Journ. de Méd. Vétérinaire*, par M. Duguy, t. ii. p. 272.)

Simple melanosis is not of itself dangerous; it causes no particular disturbance of the health, unless from its size it happen to press upon organs and produce functional disturbance. It may also be confused with cancer, or it may be attended with inflammation and ulceration of the texture, directly connected with it. By its pressure on important vessels, it may also give rise to dropsy.

Surgery possesses no means of disposing a melanotic tumour, the only plan of cure being that of removing the new production with a knife. The practicableness and propriety of this will depend upon the situation and extent of the disease, and the inconveniences experienced from it.—C.

[MYOTOMY. The danger of being the first surgeon in America, who performed myotomy, will may be contradistinguished from timidity, for the removal of deformity in a limb, belongs to Professor Paul F. Key, of Augusta, Geo. The case will be found reported in the *South Med. and Surg. Jour.*, for 1838; and consisted in the successful division of the Adductor Longus Femoris, the deformity and subsequent loss of motion in the thigh. The incision was made along the inferal edge of the muscle, commencing at the pubis, and extending in a similar direction five inches, and the muscle was then divided about three inches below its origin from the pubis. For the details and subsequent treatment, I have no space, but the success of the operation was complete. (See *Tasatomy*, Wm. Nuck, &c., in the Appendix.)

In Europe the division of the muscles has been practised of late for the reduction of long-standing dislocations, and for removing distortions of the spine: The trapezius, rhomboides, levator scapule, sacro lumbalis, and longissimus dorsi, have been subjected to myotomy. Some of these sections have been made in America, prompted by the success of M. Garcia, of Paris, but I am not informed of the results. Dr. Flint, of Louisville, in his *Notes on Dr. Smith's Faint Muscles*, lately reported by Lee and Blanchard, of Philadelphia, severely censures these various operations, and applies to these Mr. D.'s own epithet, in reference to the myotomy employed in cases of scirrhus, which he designates, "muscle-cutting-on-mad."

Dr. Matter, of Philadelphia, has lately divided the adductor and the posterior muscles in a lady, who for nine years had been deformed and crippled by their permanent contraction. The operation has been successful, and the lady is enabled to walk without crutches.

Dr. J. W. Schmidt, of New York, has cured a case of immobility of the lower jaw, by the substance division of the masseter muscle, after the movement employed by Dr. Mott, for opening the mouth in analogous cases, had been repeatedly used without success. The case was one which was dependent upon a contraction and rigidity of one of the masseters, consequential upon ulcerated sore throat, and had existed for twelve years. Dr. Carrochan, of this city, performed a similar operation, but a true ankylosis of the joint prevented its success.—Baker.]

N.

[NECROSIS. Dr. Alex. E. Hensch has a paper in the *Am. Journal of Med. Sciences*, for 1851, on the application of the caustic remedy in various diseases, from which it appears, that in the burning stage of necrosis, and when matter is established under the papilloma, so as to demand it, this suppurates the produce of laying open the tumour so as to completely expose the bone, or so much of it as is involved, and then applying the actual cautery as a white line, leaving the surface thus exposed. Dr. Hensch has treated several cases in this way with entire success.—Kearse.]

[NEURALGIA. Dr. J. C. Warren has had considerable experience in the treatment of neuralgia, and reports as follows:

"Supra-orbital nerve divided in two cases with success; the infra-orbital nerve divided in one time, and in six cases it succeeded; the facial nerve divided twice without success; and once the inferior maxillary nerve, which removed the disease.—Kearse.]

[NEUROMA, or Neurotic Tumours. Professor Parker, of New York, has distinguished three varieties.

1st. A very small tumour is at directly under the skin, and seeming to occupy the very extremities of the nervous filaments. They are very painful, especially if touched or handled, and require excision.

2d. Occupying the trunk of a large nerve. He has lately removed one from the ulnar nerve, just above the internal condyle, which had attained the size of a pullet's egg, having subsisted for several years. It was attributed to repeated blows received upon the nerve where it passes over the olecranon. None of the original filaments could be traced in the future it upon its surface, having changed into a pulpy mass, contained within the thickened and distended sheath.

3d. This variety is found upon the end of a stump, and is the source of the acute pain sometimes so distressing after amputation.

Mr. Cooper's article on this subject is entirely new, and is worthy of attention.—Kearse.]

Neuroma, (from *νῆρ*, a nerve) a term originally employed by Oiler to signify a tumour seated in or upon a nervous trunk. This subject has been ably investigated by Mr. Wood, the results of whose researches are published in the *Arch. Med. Chir. Trans.*, vol. iii. part 2. Tumours, connected with nerves, are subject to much variety. Sometimes, though rarely, the swelling consists almost entirely of a cyst, filled with a fluid, as exemplified in the case operated upon, and reported by Cheever. In other instances, it is a part solid, and in part fluid; more frequently it is solid throughout. In two of the cases I allude to by Mr. Wood, the tumour consisted almost entirely of a firm membranous cyst, containing a thick fluid; in the remaining, it consisted partly of fluid, and partly of a solid substance; and, in every, it was entirely of a solid texture. The consistency, colour, and appearance of the solid part did not differ in cases; and sometimes in different parts of the same tumour. In some instances, the whole was very firm and hard, of a whitish, or yellowish colour, and of a short-cartilaginous appearance,

harder than a nerve, and rather more shining. The fibres ran generally in a longitudinal direction, but are not always parallel, and the extremities of them were observed by Mr. Wood to be filled up by the substance of the tumour. In other cases, one part of the mass is solid, of a whitish colour, and sometimes appearing as such; and, in another part, there are cells of a larger or smaller size, some empty, others containing either fluid, or a solid, cartilaginous substance. Occasionally small lobes are met with, all distinct, but closely pressed together. In almost all cases, Mr. Wood observed a firm way, more or less dense, and of a shining appearance, not unlike tendon, and sometimes formed in part or entirely of altered tendons. In some cases, the one is loosely attached to the continued part by a thin cellular substance; in others, it is firmly incorporated with them; and sometimes it is attached to, or partially covered with muscular fibres. The nerve itself is sometimes found where it enters and comes out of the tumour; but more frequently it is thickened, and new and then reddened. The nerve may often be traced to the surface of the diseased part, and some of its fasciculi even into the substance, or side of the tumour. When, however, the swelling is very large, none of the nervous fibres can be traced from the trunk above to that below the tumour. The circumstance of the disease affecting only a certain number of the fibres of the nerve, seems to Mr. Wood to account for the constant power of sensation and motion, often retained in the limb beyond the tumour. That part of the nerve does continue adequate to its function, when another part of it is much diseased; it is proved by the effect of dividing the nervous trunk in the operation for the removal of the tumour, when the sensation and power of motion, which had previously been little impaired, became instantly destroyed, or much diminished. (See *Wood, Arch. Med. Chir. Trans.*, vol. iii.)

The pressure of a neuroma may give rise to local pain and numbness, and, in some instances, it has been known to excite convulsions and epilepsy. In a case recorded by Portal, a woman was freed from epileptic attacks by the removal of a tumour, which had formed on one of the nerves of the thalamus.

The generality of neuromatous swellings do not seem to be of a dangerous nature; "first, because however large the diseased mass is, or however long it may have existed, the contiguous nervous and more particularly the skin, do not become affected with disease of a malignant kind; and, secondly, because there seems to be no tendency to a return of the complaint after it has once been removed by operation." (Wood, *ibid.*)

We know from the history of nodular aneurism, however, and especially from the *Annals of this Society*, as it presents itself in the eye, that the nervous may be the seat of it. Thus, in this case, a neuroma is met with exhibiting a firm and bloody substance. Mr. Lawson removed from a middle-aged and healthy-looking man a tumour, which had occupied the pyramidal space for a considerable period. It was growing rapidly, had attained the size of a chicken's egg, and was seriously impeding the motions of the limb. On the

dissection, the tibial nerve was found intimately connected with it, the fibrille stretched over its sheath entering into, and being mixed with the substance of the growth. The nerve was cut above and below, and the whole mass excised, broken, and entire. During the stay of the man in the hospital, a tumour was detected on the front of the thigh of the same limb; here an inflammatory swelling took place, and suppurated. It was opened, but the original lump did not disperse. Within six months after the healing of the wound in the arm, the patient returned with an enormously swollen limb, and a large elastic nodule mass in the back part of it. A bleeding fungus protruded, and the disease was soon fatal. The original tumour, now in Mr. Liston's collection, is soft and bloody; but that in the fore-part of the thigh was firmness, round, larger than a hen's egg, and involved the anterior crural nerve. The diseased surface, which had been reproduced in the popliteal space, had all the characters of fungus hirsutissimus. It seems extraordinary, that, in this case, the removal of the tumour from the arm, with at least three inches of the tibial nerve, should not have been followed for an instant by any loss of power of motion or sensation in the limb or foot. (See *Liston on Pract. Surgery*, p. 294.)

The following advice is relative to the treatment, as offered by Mr. May, appears good. The tumour should be exposed, and if separable from the surface of the nerve should be removed, whether solid, or a cyst. If completely encapsulated with the whole structure of the nerve, and that nerve a small one, it should be removed with the portion of nerve involved with it. "If so complicated, and the nerve the sciatic, and the tumour a cyst, the cyst might be punctured, and the fluid evacuated, every precaution being taken to unite the wound by adhesion. In the last case, supposing the tumour to prove solid, another question might still arise; whether, the nerve being first divided above the tumour, the latter would not admit of being dissected out of its palisade limb, with more probability of safety to the patient, than if the nerve to be operated upon were left in communication with the limb?" (See *May's Human Physiology*, p. 148.)

An interesting account of the removal of a tumour of the radio-ulnar nerve of the right arm has been published by Dr. Gibber. The case terminated successfully, with a recovery of some slight use of the extended muscles of the fingers; and "the patient was dismissed with returning sensation in the back of the hand, and a tolerably free use of the arm." (See *Educat. Med. and Surg. Jour.*, vol. xxviii, p. 103.)

As is well known, when nerves have been divided in amputation, their extremities swell into firm balls of an oval shape, and frequently of the size of a nut. In certain instances, these enlargements of the ends of nerves often meet by mutual suffrages, and this probably, as Mr. Lawrence conceives, either from the bulbous swellings of the nerves being involved in the cicatrix, or passed by the contraction of it against the swollen end of the nerve. (See *Lawrence*, in *Med. Chir. Trans.*, vol. xvi, p. 333.) For additional remarks on this last subject, see *Evans*. No segregations of the appearances of the ends of nerves in stumps, consult P. G. Van Boon data que in *partibus Mendi* præsertim such appearance, vulgariter, notanda sunt. *Lupl. Batav.*, 1803, 310.—C.]

[NIPPLES. In addition to what is stated

upon the subject of sore nipples in the article *MAMMÆ*, I may observe, that the nitrate of silver is an excellent application for the cure of this painful and sometimes obstinate complaint. Dr. Hare, of Glasgow, strongly recommends its use in the following manner. Having gently, but carefully dried the nipple, the point is to be freely touched with a sharp pencil of nitrate of silver, which is to be suspended also into the chaps and cracks. The nipple is then to be washed with a little warm milk and water. The pain soon subsides, and the sore may then be healed with a little zinc ointment. Dr. Hare occasionally washes the nipple with a saturated solution of borax before and after suckling the infant. (See *Lond. Med. Gaz.*, vol. xiv, p. 871.) Sir Aschley Cooper's formula of ointment for these cases is specified in the article *MAMMÆ*. Dr. Wilson adds his testimony in favour of nitrate of silver. (*Op.*, et vol. cit. p. 733.) Pyroligneous acid, blended with yolk of egg, is another remedy sometimes preferred. (*Gaz. Medicale*,) —C.]

[NOVI MATERNI. Dr. J. Rhea Barton, of Philadelphia, has for a number of years practised an operation for these deformities, when accidental, by inserting two pins at right angles through the base of the tumour, and then encircling these with a ligature. The pins form four fixed points, beneath which the ligature may be tightly drawn, and a neck is thus formed even upon those flattened breasts. Some of the English surgeons have adopted a similar practice, but as Dr. Barton used it in Philadelphia simultaneously with the intelligence that a similar operation was performed in England, I am unable to decide the claim of priority, though it was original on the part of Dr. Barton, he having devised and executed it before he had ever heard of its being elsewhere thought of. His success has been very gratifying in numerous cases.

Dr. J. C. Warren has had extensive experience in the removal of these affections, having removed three by caustic, eight by ligature, and eighty-five by excision, all of them successful; although in one case he found it necessary to practise excision twice. See his splendid work on Tumours, for interesting cases of aneurisms by anastomoses.

Dr. A. B. Stevens prefers a peculiar form of scissor for the removal of most of the mammalian variety. He passes an armed needle longitudinally through the tumour, having attached to the extremity of the thread a thickened ligature, composed of strong bibles together until their bulk is sufficient to plug up both the openings made by the entrance and exit of the needle. In this way he avoids all hemorrhage, by drawing the needle through quickly, secluding the thickened ligature, and leaving the litter. Inflammation and suppuration take place within the cavity thus formed by the scissor, and obliterate it completely. There are this civilized surgeon remove such deformities from the face, in positions to which neither of Dr. Warren's methods were adapted, and either of them, if successful, must have sadly disfigured by the operation, while the method leaves scarcely any trace of the operation.

Dr. Mott professes, in all these cases, the employment of acupuncture with needles, heated to a white heat by the flame of a spirit lamp, a practice introduced by the late Dr. Bosc. He passes these hot needles directly

through these anastomosing tumours, some eight or ten times in different and opposite directions. Not a drop of blood flowed, the pain is very inconsiderable, and I have had the opportunity of witnessing his success in repeated instances. The effect of this asphyxiation upon the tumour is like the seton, and leaves scarcely any scar.

Dr. John Watson, of New York, has published in the *American Journal*, for 1839, a critical paper on the nature and treatment of Telangiectasis, or that morbid state of the blood-vessels which gives rise to naevus and aneurism from anastomosis. This barbarous specimen of technology was filched originally by Græfe, as a synchysis for the nervous anastomosis of the older writers; the aneurism from anastomosis of John Bell; the tumour varicose or foetiform sanguine of Boyer; and the tumour verrucosus of Dapuytren. My limits will not permit me to refer to this valuable article of Dr. Watson, which abounds with discriminating good sense and practical information on this obscure and difficult topic.—*BRISTOL.*

[NOSE. HYPERTROPHY, OR LIPOMA OF THE.—The growth, or enlargement, seems to be restricted to the skin and subcutaneous cellular tissue. These textures become thickened; and the sebaceous crypts are enlarged and disordered with their secretion, some of them to a considerable degree, and forming encysted tumours of the size of a garden pea; the cellular tissue is loaded with serosity, and, in some places, there is fibrinous deposit. The arterial capillaries are not much enlarged; but, when the part is dependent, or the circulation much excited, or the return of blood prevented by violent exertion of the lungs, the veins are much enlarged, giving the tumour a more blue and distended appearance. Different parts become affected in succession, and the mass is made up of many growths from the point and sides, of various sizes, separated by fissures, in which the sebaceous secretion, often rancid and offensive, lodges. These excrescences, though attached by pretty broad bases, are loose and pendulous." (See *Liston on Prost. Surgery*, p. 237.)

In some instances, the tumour has been known to extend over the mouth and nostrils so much, that the patient could not breathe well, especially during sleep, unless a tin tube was placed in one of the nostrils. If the tumour were not supported with the hand, it also became impeded in any liquid that was brought towards the mouth to be drunk. (See *Hey's Surgery*, ed. 2, p. 263.)

In one of the cases, under this last partitioner, the case appeared to be nothing more than an enlargement of the common integuments of the nose. The bones and cartilages seemed to be in their natural state. For, though the latter were buried in the mass, yet, when the tumour was supported, Mr. Hey could distinctly trace, with his finger, the border of the cartilages. The tumour was divided in the middle; and at the origin of this slit, he could discern a small portion of the tip of the nose. The sebaceous crypts were so much enlarged, that some of them would admit the end of a crow's quill. Mr. Hey operated as follows.—During full, with his finger, the border of the cartilaginous part, which gives the nose its proper figure, he marked out this border upon the inferior surface of the tumour, with a pencil moistened with Indian ink. Then, allowing for the thickness of the cartilage, and a

proper covering of adipose membrane, he made his first incision parallel to the line marked out. He next pursued the dissection upwards, aiming at preserving the natural figure of the nose. When the principal artery had been removed, he detached the remaining part of the adipose substance in an even surface by means of the toothed scissors. The hemorrhage, which was considerable, was stopped during the operation by the pressure of the fingers of the assistants. The patient, though a stout man, nearly fainted from the loss of blood; but, after the completion of the operation, the bleeding did not return. The case succeeded perfectly.

I have seen the operation performed in one or two instances by Mr. Liston. The following is the method preferred by him. "An incision should be made through the diseased integument and cellular tissue at the medial line upon the cartilage of the apex and columella, not however so as quite to reach them. An assistant places his forefinger in the nostril, and the surgeon, seizing the mass with his fingers, or with a small vulsellum, proceeds to dissect it off with a scalpel. The incisions must be carried pretty close to the cartilages of the ala, until the one side is cleared, the edge of the opening being well observed, and neither than, nor the cavity ever exposed open. The assistant will give warning, if the knife, at any stage of the proceeding, approaches his finger. The surface is trimmed a little, if scabrous requires, with a pair of thin slightly curved, or knife-edged scissors. A similar proceeding is observed on the opposite side, and they (the two sides) are to be made as symmetrical as possible. A few vessels may bleed: but the bleeding is easily restrained, during the dissection, by placing the small spring forceps (Græfe's) upon their mouths, or they are compressed by the point of the finger. Ligatures are afterwards placed upon them if they still persist in bleeding. Should the ligatures not hold, the cut ends (of the vessels) not being readily drawn out from the congested tissue, a fine canining needle may be passed across the bleeding point, and a ligature tied under it, the ends of both the needle and thread being cut off. Any troublesome general oozing may be stopped by plunging the anterior nares, applying a compress of lint, and a double-headed roller. Difficulty and pain are experienced in removing this dressing, and it is much better, if possible, to apply frequently and assiduously for a few hours, pledgets of lint, moistened with cold water, and after copious discharge has ceased, to substitute the tepid dressing, and thus encourage suppuration as speedily as possible." The exposed surface having granulated, the resolution may be used. Mr. Liston has removed many of these growths without any untoward accident. In only a single case, a repetition of the operation became necessary after an interval of nine or ten years. A tumour of large size had been removed from the apex of the nose, leaving the integuments of the ala slightly thickened. These afterwards increased so as to form a bulky swelling on each side of the nostril. (See *Lipoma's Practical Surgery*, p. 246.)

See also Crozier, in *Mém. de l'Acad. de Chir.*, t. iii. p. 517. *Robert Delorme, New Progress of Surgery in France*; translated by T. Chenevix-Treadwell, 4to, Lond. 1860.

Nose, Hemorrhage from, Epistaxis. In consequence of the bleeding being sometimes profuse, and incapable of being stopped by other means, it becomes necessary to plug up the nostril

and corresponding posterior opening of the nasal fossa. A loop of wire, or a strap, may be introduced along the floor of the nostril from below, backwards; and when it reaches the pharynx, it may be taken hold of with a pair of forceps, and brought forwards in the mouth, so as to allow a strong ligature to be attached to it, which is next drawn into the nasal fossa, and out of the nostril, by means of the wire, or bougie. This now becomes useless, and may be cut off. To the middle of the ligature, a loop of lint is fastened, and the ligature being then drawn more out of the nostril, fixes the lint in the posterior aperture of the nose. The nostril itself is then to be closed with a plug of lint. The dorsal of lint may easily be removed from the posterior opening, when no longer required, by displacing it with a probe introduced through the nostril, and the end of the portion of the ligature in the mouth. This part of the ligature should be kept against the roof of the mouth, by fastening it to the upper lip with a piece of adhesive plaster. A still more simple mode is to use a loop of catgut, which will pass to the back of the fauces as readily as wire, or a bougie, and one portion of it being then drawn forwards out of the mouth, will serve for the conveyance of the plug of lint to the posterior opening of the nasal fossa.

NOTE. Operation for the division of. The Taghiaroti method, which consisted in employing a portion of the integuments of the forearm for this purpose, is now superseded by the original plan, in which the excized remains of the former nose are reversed into fresh surfaces, and a flap of skin, duly shaped, is twisted, and brought down from the forehead, so as to admit of being united to them. This is the rhinoplastic art, as it is termed, from *rhis*, the nose, and *plastis*, to form, which has been practised in India time immemorial, and for many centuries in Italy, where cutting off the nose was a common punishment for certain offences, even as long ago as the period of the ancient Romans. The following is the mode adopted by Mr. Liston.—"A piece of soft leather, cut to the shape and size of the integument required to replace the apex and alae, is placed flat upon the forehead. To secure accuracy in the line of incision, its boundaries are marked on the skin with ink, in case the patient prove unsteady. The flap being thus defined, is dissected down, and kept of uniform thickness, till near the lower angle, when the incision should be carried deeply, so as to ensure an abundant vascular supply. Care should be taken, however, to avoid the pericosteum, for otherwise absorption may follow, which would increase the scar, and render the cure tedious. This narrow part of the flap, or attachment at the root of the nose, must be of some length, to allow

of its being twisted, so as to bring the integument to the exterior, when the part is adapted to its new situation; and to facilitate this, the knife should be carried a little lower down on that side on which it is intended to make the turn. After the bleeding has ceased, the flap is retained in apposition with the raw edges of the truncated organ, by points of suture. A little rolled lint is placed in the nostrils to support the flap, but no other dressing should be applied. The surgeon should be in no hurry to fix the flap; for union is most likely to occur when bleeding has ceased, and the edges of the wounds have begun to assume the glial apposition, which prevents secretion. The lower part of the wound in the forehead is brought together by suture. To the rest, lint moistened with warm water, and covered with oiled silk, is applied, the lint being renewed from time to time. As for the nose itself, the lint may be removed in three or four days, and then too perhaps some of the stitches may be dispensed with. The flap will be found sufficient, yet movable with the mouth. During the cure, contraction of the nostrils is prevented with tubes. When the nose is firmly consolidated, and a collateral circulation has been established, so as to become independent of the supply of blood through the twisted attachment, this is to be divided with a bistoury, so as to remove a wedge-like portion, and let the front of it be laid down smoothly over the root of the nose. With respect to the columella, the practice in India was to obtain this by taking a slip from the forehead, along with the rest of the flap; but Mr. Liston has found it much better first to form the main portion of the nose, as already described; and, after this has become consolidated, to raise a columella from the upper lip. The inner surface of the apex is first pared. A sharp-pointed bistoury is then passed through the upper lip, previously stretched and raised by an assistant, close to the remains of the former columella. The incision is continued down to the free margin of the lip; and a similar one, parallel to the former, is made on the opposite side of the central line, so as to make a flap about a quarter of an inch in breadth. The incision is then divided, and the protrusion of the flap removed. The new columella is then fixed in its proper place with a sewing needle, which after its head has been covered with sealing-wax, to facilitate its introduction, is passed from without through the apex of the nose, and obliquely through the extremity of the elevated flap. Then a few fucus of thermal surface to keep the fresh-cut surfaces in contact. Twisting the flap is here unnecessary. Lastly, the edges of the wound on the lip are to be brought together with the twisted suture. (See HARRIS and LESTER'S *Practical Surgery*, p. 213.)

O.

OPHTHALMIA. Professor DUGES, of Gen., has a paper in the *Smith. Med. and Surg. Jour.* for 1836, on purulent ophthalmia, which relates several cases, all of which were successfully treated by a solution of chloride of soda as a wash, one half an ounce to a quart of water. He was led to employ it, by reflecting upon the

anti-suppurative properties of the article, which are so well known to every practitioner.

Dr. DONN PIERCE, of Philadelphia, has published in the *Med. Exam.* for April 1842, a paper on the iodide of potassium in ophthalmic diseases. The dose he recommends is from two to six grains, three times a day, in a table-spoon.

nd of the compound drug of sarsaparilla. It is said to possess great potency in relieving the arthralgic pain in the eyes, temples, and head, which are often present in inflammatory affections, involving the deep tissues of the eye. In granular conjunctivitis, scleritis, trichiasis, and strabismic inflammation it proved successful.—*Rexas.*

ORTHOPEDIC. This new surgical specialty, though so lately introduced, seems to promise the successful removal of nearly all the deformities of the human body, however extensive or complicated, and a better moral or congenital. Under the several articles on Cholera, Strabismus, Wry-neck, Pterygium, Myotomy, &c., it will be seen that American surgeons have been diligently occupied in this novel department of surgery, and with a boldness and success which will compare with the achievements of any of their transatlantic contemporaries. I must refer to these several articles for the operative, improvements, and success, which have crowned their exertions, so far as they have reached me. Among those who have cultivated this branch in America, I may name Dr. Nico, Delmott, Parker, Muller, Paterson, Dixon, Eise, Gross, Fox, Smith, Davenport, Walter, Dex, and many others.—*Rexas.*

OSTEOSARCOMA. Under the head of Tumors, Excision of Bones, Jaw-bone, and Amputation, a number of cases of this disease are related, removed by operation, and among these Dr. Moir's excision of the clavicula in 1828, and the lower jaw in 1821; Dr. Sisson's operation on the upper jaw in 1825, and extirpation of the ischiopubic in 1828. Dr. Murray's removal of the scapula and clavicle together in 1833, and the repetition of this last operation by Dr. McClellan, are worthy of notice.—*Rexas.*

OVARY. This organ may be converted, 1. into a single cyst, which will sometimes acquire such magnitude as to fill the whole of the abdomen, and to cause a swelling resembling that of ascites. Cruveilhier deems it probable, that in this case the enlargement of one vesicle of the ovary has elaborated the rest of the organ, which is found to be in the state of atrophy at some point of the circumference of the cyst, and contracted with emaciation and osseous deposits. 2. There may be a single pouch, as in the foregoing instance, but from the inner surface arise suppressed growths of various dimensions, composed of a substance having the consistency of the vitreous humor, or of that of the crystalline lens, and contained in irregular fibrous cells. In the first example the fluid in the cyst is usually limpid; in the second, viscid like white of an egg, or tremulous as jelly, and incapable of being discharged by puncture. 3. The tumour may be divided into a multilocular cyst, or pouches, filled by nature at different kinds, as limpid serum, a viscid albuminous fluid, a reddish gelatinous or a bloody purulent fluid. Cruveilhier has found many of these cysts filled with a *dyctaceous substance*. Indeed, in tracing the accidental formation of tumour structures, intimate as that he has met with numerous cysts, the structure of which was more like that of a tumour than a serous membrane, and Meckel makes a similar remark. (See *Journal, Anat. Pathol.*, t. vi. p. 264.) It is not unusual to find one, two, or three of the cysts, forming a half, two thirds, or three fourths of the swelling. The cysts may be perfectly distinct from one another, or in groups, with sym-

metrisms between them. 4. *Acephalocysts*. 5. Cysts containing hairs and no albuminous substance. 6. Ovarial cysts, containing a keratin, or portion of it. Mr. Williams, of Bethleh, lately informed me of an ovarian abscess from which he removed a full grown tooth. Under Mr. Gunting, in St. George's, and elsewhere Dr. Block, of Washington, I have seen cases in which the bones of fetal subjects were extracted from similar abscesses. 7. Cysts, resting upon a cancerous base. (See *Cruveilhier, Anat. Pathol.*, t. vii. livr. four.)

This author relates the particulars of a case where an ovary transformed into many pouches, all filled with a gelatinous substance, was equivalent for ascites, and peritoneal effusion. An encysted copy of the ovary at its early stage is easily distinguished from ascites. The circumscribed form of the cyst or encysted ascites character of it, wherever situated. As for the development of the cyst or encysted ascites—a circumstance generally specified as a test—Cruveilhier regards it as theoretical and doubtful, because the cyst, as it increases in size, extends towards the central line, where there is the least resistance. But, when the cyst fills the whole of the abdomen, the criterion of its circumscribed form can no longer be applied. Then the disease will not admit of being distinguished from ascites, either by the size or shape of the tumour. The following considerations will have thrown light on the diagnosis: Ascites is seldom an idiopathic affection, being generally dependent upon organic disease of the abdominal viscera, or connected with peritonitis, whereas ovarian dropsy is almost always a local disease, frequently existing while all the other organs are healthy. In ascites the fluid always gravitates to the lower portion; hence, when the patient is lying down, the fluid descends towards the pelvis and lumbar region. The small intestines lie, as Frank has explained, in the umbilical region, the neck of the colon, and the stomach in the epigastric. Tap the belly gently with the finger, or with the ivory plate of M. Foery, and the sound will be dull in the hypogastrium and loins; and the flat or dull sound will change its place according to the varying position of the fluid in the different positions of the patient; but the sound will always be dull in the umbilical and epigastric regions. On the contrary, in encysted dropsy of the ovary, the cyst is developed in front of the bowels, so that the gaseous sound can never be perceived in front of them; an observation first made by M. Rosten. The fluctuation is never so limited as in ovarian dropsy as in ascites, but of a softer kind. In ascites the neck of the uterus remains in its natural place. In ovarian cases the uterus is not propelled down, as usually stated, but displaced upwards; and in this case, the cavity of the pelvis is filled with a tumour which is an appendage of the abdominal swelling. Ascites rarely exists without visceral disease and rupture of the lower extremities, a symptom frequently absent in ovarian cases.

When the ovary is transformed into *ovocysts*, the fluctuation is generally obscure; but in many cases, the bulgings of the tumour may be discerned, either through the parietes of the abdomen, or through the vagina, or uterus. Cruveilhier advocates the operation of paracentesis never to make a puncture unless the fluctuation be very distinct. A puncture, he thinks, can only be of service when there is a cyst of serous

fluid. "The distinctions (he adds) of single and multiplied cysts would be very important if the extirpation of the ovary were to become an approved operation. The latter should not be modified with; the former alone admitting of extirpation when their contents have been discharged, and a moderate incision is made in the parietes of the abdomen." See *Cruikshank*, vol. vi. livr. 3me.)

Ovarian cysts and tumours are exceedingly common, and are often met with in young and middle-aged women, both single and married. Dr. Barlow gives an instance in which each ovary was found connected into one or twelve cysts in a girl only ten or twelve years of age. (See *Proc. Med. Trans.*, vol. iv. p. 434.) The rate at which the disease advances, varies in different cases. Sometimes it does not attain a very large size till some years have elapsed; in other instances its augmentation is rapid. In the latter circumstances, the evolution is usually considerable. A patient under me at the *Biscuitary Dispensary*, whom I used formerly to tap about once every two months, has remained with the disease in nearly a stationary condition for the last five years, having become tired of repeated operations. I have generally found, that the danger is more in relation to the quality of the fluid than the size of the swelling. If thick, dark-coloured, and very viscidous, parietal cysts only afford temporary relief; and the repetition of it is sooner or later followed by inflammation within the cyst, and fatal disturbance.

The growth of some ovarian tumours, if in their early stage, and, as Dr. Barlow thinks, while the organic transformation of the part has not advanced too far, sometimes terminates in cure of being checked. Nay, in some cases reported by this gentleman, prove, ovarian dropsy is not always absolutely incurable. The means which he found most useful were moderate local or general bleedings, whenever pain and irritation came on; blisters, or leeches; belladonna plaster, digitalis, and iodic. In some cases, I have presented the hydrate of potash, but never with decided success. I have often known the pain and irritation relieved by cupping, alsters, purgatives, and the preparations of morphia.

Under the head of *Parovestria*, I will notice the operative expedients for the relief in case of ovarian dropsy.

On ovarian cysts, which are most commonly, but not always, of the kind called fibrous, Delpech offers many cases, accompanied by observations. (See *Chirurgie Obstétr.*, t. ii. 60, 1825.) In one of his dissections, a *stroma* and a *honey* cyst were both found connected with the ovary; a case which he deems exceedingly rare. He affirms that the cure of an ovarian cyst has never been observed, whether as the work of nature or art, and nothing can be cited that would justify any comparison with the spontaneous or artificial terminations of the *adenomata* and *honey* cysts. From the sites and dissections of ovarian cysts which he presents, he deduces, amongst other inferences, the following:—1. They are the product of a particular and accidental organization, and by no means of the gradual dilatation of the natural vessels of the ovary. 2. Observation has not yet sufficiently proved, whether, under favourable circumstances, this, is any other kind of cyst of the ovary, is ever formed alone, unaccompanied by any other change of this organ. 3. Most frequently cancer is at the same time developed;

masses of this nature existing either upon or between the layers of the cyst. Here I must observe, that the sarcomatous substances, so commonly attending ovarian cysts, are not usually regarded by British surgeons as truly carcinomatous; nor am I disposed that Delpech brings any proof of the correctness of this part of his observations. The question is also a material one, inasmuch as it has great influence on the practical point, whether parietal and other active measures should be undertaken or not! 4. The statement, that there are always several cysts, does not agree with Dr. Baillie's account of the whole ovary being sometimes converted into a capsule. (Worcester, by Warren, vol. ii. p. 315.) In their structure they are alike, though their parietes may differ in thickness; but the nature of the matter which one cyst contains may be very different from what is included in another, independently of the effect of any incidental inflammation. This remark coincides with what Dr. Baillie has said on the same point. 5. Only one cyst attains a vast magnitude, so as to fill the cavity of the abdomen; and, though the others increase, they do not exceed a middling size. 6. The parietes of the cysts do not become thin in proportion to their distension; but, on the contrary, grow thicker. 7. The cysts communicate with one another only accidentally. This disposition is sometimes retained after parietal, or some other surgical proceeding, calculated to produce an inflammation of some duration in the morbid mass; but Delpech thinks, that we have no ground for presuming that it ever happens spontaneously, and from the mere effect of distension or ulceration. 8. For the most part, the origin of the disease is quite obscure; the swelling being the only thing at first taken notice of. If pains are sometimes experienced in the situation of the ovary, or in that of the uterus, it is not till the tumour has made considerable progress, and has been of long standing. Such pains are always exceedingly vague, and only manifested by some sympathetic ailment; and it may be doubted whether they may not rather depend upon distention, than organic disease. At all events, nothing justifies the suspicion of their dependence upon inflammation. 9. Inflammation sometimes originates spontaneously in an ovary containing cysts; but, more frequently, its cause is judiciously treated. Hence arise particular symptoms, readily distinguished from such as belong to the organic disease. Dissections evince that the inflammation leads to a deposit of different quantities of concrete inflammation matter, or pus, in only some of the cysts. And Delpech believes that the inflammatory process does not readily establish itself, nor easily spread to the whole mass of an ovary in this state. 10. An ovarian cyst may rupture in such a degree, that the whole abdomen is filled by it. When the surrounding peritoneum is frayed, the cyst may become adherent to all the viscera, and to the parietes of the belly. Under these circumstances its strength is augmented by the support of all the surrounding parts; and, if inflammation be kept off, and the accompanying debilitated valvulae should not increase, the disease may remain stationary for many years. 11. The cyst may burst, and some of its contents pass into the peritoneum, where a dangerous inflammation may be the consequence. Several examples of this occurrence are recorded by Delpech. 12. The ovarian can-

hardly be recognized with certainty by the symptoms; but it is to be apprehended when the tumour augments rapidly, attended with acute fixed pain. 12. Here the project of treatment will depend upon the circumstances of the figure. When absorption of the extravasated fluid ensues, the surgeon will be prudent not to interfere much; but, if this desirable event should not take place, Delpech recommends paracentesis to be performed on the opposite side. 13. As no doubt is known that will cause organic disease of the ovary, and active medicines create serious irritation in the abdominal viscera, which Delpech describes as practically infeasible in this disorder, he lays it down as a fundamental rule in practice, that they ought not to be employed. 14. As puncturing the tumour, when a fluctuation is evident, creates a risk of lingering on peritonitis, or such hemorrhage as cannot be commanded, the operation should never be done for the first time, unless the cyst be about to give way. Delpech advises the puncture to be generally made at the side of the hypogastrium, corresponding to the diseased ovary. If, however, the fluctuation should be plain at the bottom of the vagina, and the tumour should not quit this place, at the different attitudes of the patient, he considers that this is the most advantageous situation for the puncture. If the cyst should form a projection at the vulva, so, sometimes happens, this spot should be selected. 15. A puncture may be undertaken with more confidence, when one has been previously made without all success or, provided care be taken to make the opening properly in the situation of the former. 16. In these last cases, if the patient's strength be not too much reduced, Delpech sanctions the attempt to establish an artificial fistula, by leaving a gum catheter in the puncture; but if inflammation come on, the scheme is to be renounced. 17. Le Boen's operation of making a free incision into the cyst (see *Paracentesis*) is condemned, as likely to excite peritonitis. This consequence, he claims, the more likely is follow, as experience proves, that such treatment produces extensive mortification of the cyst. 18. An inflammation of the large cavity of the cyst, he conceives, is sometimes the cause of death, even without peritonitis. 19. Everything that is known respecting ovarian cysts, proves to Delpech that they are incapable of undergoing the kind of distension which takes place in the sero-mucous ones; that, when punctured and kept open, whether they inflame or not, they subside, and are thrown into folds, but still retain their cavity, and the property of secreting the same fluid as heretofore; that, when the puncture closes, the cyst fills and expands again, sometimes with an unusual degree of pain, in consequence of the adhesions formed in its empty state; that the punctured part then generally reopens spontaneously; that the inflammation, caused by opening the cyst with a history, is not more affected in lessening or increasing inflammation, than what follows either a simple puncture, or this plan, succeeded by that of keeping up a fistulous aperture; that the practice of an incision, and its consequent perils, have most frequently only terminated in the formation of such an opening; that, in a few rare examples, in which the operation produced a complete obliteration of the cavity, the whole cyst was destroyed by exposure. 20. The project of treating an ovarian cyst like a lymphatic,

is strongly disapproved of by Delpech, with whose opinion the observation of some attempts, of this kind leads me fully to coincide. (See *Paracentesis*.)

It appears to me, that notwithstanding the possibility of the accident, Delpech overrates the danger of internal hemorrhage, from puncturing an ovarian cyst; and that he ought to have admitted the severe indigestion, the oppression of breathing, the retention of urine, and other urgent symptoms, often produced by the great pressure of the swelling, as circumstances rendering the operation indispensable for the present relief of the patient. Sir Astley Cooper informs me, that he has not met with any fatal case from piercing the cyst. In one instance, to which I was called by Dr. Egge, I punctured an ovarian cyst through the linea alba, and the fluid discharged was considerably mixed with blood; but, as the lady was not opened after death, it was unknown whence the blood had proceeded, or whether any accumulation of blood had taken place in the cyst; an occurrence, of which Delpech had such apprehensions. The reader may justly compute what has been here said with that part of the article *Paracentesis* which treats of ovarian dropsy.—C.

OVARIAN TUMOURS. In addition to the cases named in my note is contained in the body of this Dictionary, Dr. Allan Goldsmith of New York has operated successfully by excision, and the case is recorded in the *N. A. Med. and Surg. Jour.* for 1824. Since that time Dr. Goldsmith has reported this operation in two cases, one of which was completely successful, but the other failed, solely, as he thinks, because he relied upon the original ligature, which gave way some days after the operation, and the patient died, in consequence of secondary hemorrhage within the abdominal cavity.

Dr. Goldsmith relates a case in which he was concerned with the late Dr. McDowell of New York, who was the first in this country to excise ovarian tumours, and who performed the operation often, and with great success, than any other surgeon either in the old or new world. A woman who had long suffered from tumour, and had performed the operation of tapping upon herself no less than sixty times, during a few years, having learned the use of the trepan and cautery to perfection, applied to Dr. McDowell for a tumour which she supposed to be the cause of her dropsy, and begged him to cut it out. Dr. McDowell could feel a tumour of large size, occupying the site of a diseased ovary, and from its locality, proximity to the abdominal walls, and seemingly detached condition, decided upon the practicability of its removal. Both he and Dr. Goldsmith regarded the tumour as purely ovarian, and thought the *ligamentum ovarium*, that they were attended, on opening the abdomen, to discover, that what they took to be a tumour was a mass of the intestines conglutinated by adhesions, so as to present through the abdominal walls the aspect of a tumour, and utterly deceive the touch. They abandoned the operation, which might be called an exploring one, and the woman died. This case goes to confirm the doctrine taught in the text by Mr. Cooper, that if there were no other reason against the attempt to excise ovarian tumours, the difficulty, not to say the impossibility, of making out a clear and safe diagnosis constitutes in itself a sufficient objection to the operation. I have known it number of these "exploring" opera-

ties," as they are called, result disastrously like Dr. McDowell's case, for in several instances the operation has been abandoned, but the patient has died upon the table. To cut into the abdomen on an exploring expedition may well be regarded as of questionable morality, and is "most villainous surgery."

Professor Munsey, of Cincinnati, reports a case in which he performed a successful operation for ovarian disease by opening the ear, and effecting adhesion between its walls. His paper abounds with accurate and just criticism on the question of attempting the removal of these tumors. See *Am. Jour.* for 1838.—*Rem.*

[OXYMURATIC ACID.] Besides the nitrous and nitric acids, other medicines containing a large proportion of oxygen, and easy of decomposition, have been recommended as remedies for the cerebral disease; viz., oxygenated vinegar, oxalic acid, oxygenated muriate of potash, &c. (See *Cutler's Medical Treatise*, vol. i. p. 111.) But, perhaps, nothing has been put to the test of experiment with greater expectation of success, than the oxygenated muriatic acid. Mr. Cruickshank made a very early trial of it in syphilitic cases, and, as is alleged, with the utmost benefit. He also employed the nitric acid, and the oxygenated muriate of potash, and found

them eligible remedies. The latter medicine was likewise given by M. Alyon in cases of chancre and secondary ulcers, who found the good effects from it more expeditious, and more certain than those of any mercurial preparation. (*Essai sur les Progrès Médicinaux de l'Oxygène*, 4e. édit., Paris, an 12ème.) On the other hand, as much contrariety of sentiment, respecting the real and permanent efficacy of all these medicines, prevails in the numerous reports about them, as in the accounts delivered of the effects of the arsenic and nitric acid; and therefore I do not think that the reader, after the copious statements given in this book concerning the nitric and carbonic acids, (see *these words*;) would be pleased to hear again a repetition of very similar contradictions respecting the oxygenated muriatic acid. I may observe, however, that if oxygen be the principle on which the efficacy of many antisyphilitic remedies truly depends, this acid must possess greater virtue than the common muriatic acid. From me to oil, mixed in trifling quantities with sugar, may be taken in divided doses in the course of the day.

Oxygenated muriatic acid was strongly praised by Guyton de Mours as a means of disinfecting sick-rooms, and purifying the air of crowded hospitals.—*C.*

P

[PALATE, CONGENITAL FISSURE OF THE.] This presents itself in three forms:—1. Where there is a simple slit in the middle of the velum, without any loss of substance, or any fissure in the hard part of the palate. 2. With partial division of the hard palate, or roof of the mouth. 3. With complete division of the same part, in which case there is always a groove or lesser interspace between the two halves of it; and almost constantly likewise a fissure in the alveolar process and the lip. Hence, there are three kinds of operation, each of which is adapted to the particular variety of this congenital imperfection. 1. *Staphyloplasty*, applicable to examples, in which there is merely a narrow fissure in the soft palate. *Staphyloplasty*, when there is a wide rent resembling a loose substance, and unsupportive, calculated for cases in which there is a real or a seeming loss of substance in the roof of the mouth.

1. *Staphyloplasty*, pattern of M. Roux.—The apparatus required consists, 1. Of three broad British ligatures, composed of three or four strong threads. 2. Of six small curved flat needles, two for each ligature. 3. A point-screw. 4. A pair of dressing forceps. 5. A point-pointed lancet. 6. Scissors with long handles and short blades, bent laterally to an oblique angle.

The patient being seated opposite the light, and the mouth kept open, the surgeon takes hold of the right edge of the fissure with the forceps held in his left hand, while, with the right, he converts into the pharynx the point-screw, armed with a needle, the point of which is of course turned forwards. The point of the needle is then carried back to the posterior surface of the velum, and passed through it from behind forwards, near the lower end of it, and about three or four lines from the margin of the slit. The point of the needle is to be passed on as

far as practicable, and then taken hold of with the forceps. The point-screw being now removed, the needle is drawn into the mouth with the forceps, and along with it the ligature, with which it is threaded. After the patient has recovered his tranquillity and washed out his mouth, the other end of the ligature is to be passed in a similar way through the left side of the velum, and the two ends are to be brought out of the mouth at the commissure of the lips. Then a second ligature is to be applied near the angle where the two sides of the velum meet, and a third at the middle point between the other two ligatures. The left side of the fissure is then closed, depressed, and rendered concave with the ring-handled forceps, and the position of its margin begins with the curved scissors; and completed with a straight probe bluntly applied on the outer side of the forceps, and with its back directed towards the root of the tongue. Thus a slip is to be removed about half a line in breadth. Particular care must be taken to let this slip extend a little above the front angle of the fissure. The same precautions are to be followed on the opposite side; the two incisions being made to join at an acute angle above the point just now specified. It only remains to tie the ligatures. The surgeon begins with the foremost one, which is first to be tied in a simple knot. As soon as this has been duly tightened with the fore fingers, it is to be taken hold of with the ring-handled forceps, and kept from slipping, until another knot is made. The same plan is to be adopted with regard to the two upper ligatures. Finally, the two ends of each ligature are to be cut off with the scissors as usual.

No dressings are required, but the patient must refrain from talking, and as much as possible from swallowing even his spittle, which should be received in a vessel or on a handkerchief, in

proportion as it is secreted. Coughing, laughing, sneezing, &c., must likewise be avoided. Between the third and fourth days, one or both the upper ligatures may be taken away; but the lower one should be left a day or two longer. If the attempt at union fail above, which frequently happens, when the fissure extends into the roof of the mouth, the chance of it may yet be effected by the work of time, or it may be promoted by touching its edges with the nitrate of silver.

To the foregoing plan it is objected that, by passing the needles from behind forwards with their points out of sight, it is difficult to enter them with precision in the most desirable places. That when the ligatures have been introduced, the removal of the margins of the fissure, as executed by M. Roux, is exceedingly difficult. In fact, says M. Malgaigne, whatever pains be taken to stretch and draw downwards and inwards each end of the soft palate, it is always difficult, when the suture is tight with the loose margin of the velum, to make a clean and regular incision through it; and if scissors are employed, there is a risk of cutting the threads. See *Med. et Nat. Oper.*, p. 472—473.

M. Syme's Method.—The surgeon seizes the left margin of the fissure with a pair of sea-sawing forceps held in the left hand. With the right he holds the needle with the dressing forceps, the sharpness of the needle being turned towards the free edge of the fissure. The needle is introduced from before backwards on a level with the upper angle of the slit, nearly three lines to the outer side of its free edge, and it is pushed on till the whole of its curved portion has traversed the velum. Its curve points its point to be directed backwards and inwards, and to become visible in the fissure. The operator now relinquishes the free edge of the velum, and with the same forceps, which were to keep it tense, he takes hold of the part of the needle projecting backwards. A slight traction backwards and towards the side opposite that of the entrance of the needle, serves to disengage its head; and the needle is then brought from behind forwards through the fissure, and near out of the mouth, together with the ligature connected with it. Another ligature is now passed in a similar manner through the right lip of the fissure. The second needle draws a ligature after it in the form of a noose, which is detached from the needle, and the deep end of the ligature passed through it. A second or a third noose is made in the same way according to the extent of the fissure, care being taken to enter each needle about three lines from the free margin of the division. The tissues being now drawn down to keep the ligatures out of the way of the lips, the left side of the fissure is once more taken hold of with the forceps, and its edges removed with a bistoury, which is passed through the soft palate one line above the angle of the fissure, with its back towards the end of the mouth, and its edge downwards. The same proceeding is adapted to the other side, and the ligatures tied.

Mr. J. E. Smith's Method.—This gentleman, a surgeon in the United States, employs a very simple needle, mounted on a handle, and with a curve, the radius of which is about half an inch. At two or three lines from its point is a slit open at its posterior end, extending along one side of the needle to its middle. In front of this eye or slit the needle is broader than be-

hind, which facilitates the passage of the pin of the instrument which follows. The eye being laid the ligature introduced through it, the curved portion of the needle is carried out the mouth beyond the palatine fissure, and its point carried behind the middle of the velum, and passed through the latter part even behind forwards. As soon as the point of the needle has passed sufficiently forwards, and the ligature in the slit of the instrument is passed, the thread is to be taken hold of with a compression, and having been discharged from the eye, or slit in the needle, the latter instrument is withdrawn. A second ligature is to be passed half an inch higher up, and it encloses a third, at an equal distance from the second. With the ends of the ligatures passed through the urethra, this part is now drawn forwards, and the fissure in the soft palate having been thus brought nearly into a horizontal position, its edges are to be cut off with scissors, either straight or curved laterally, or with the aid of a knife and a pair of forceps. After the ligatures have been tied, they are to be cut off near the knots.

Mr. Liston's Method.—A narrow sharp-pointed handle, held by the farther end of the handle, is introduced through the edge of the fissure at its anterior margin, and run back to the apex of the open half of the urethra. This may be tied hold of, and made tense by means of the sharp-pointed forceps. The same proceeding is repeated on the other side. The ligatures are introduced with needles, fixed in handles, and of different sizes and curvatures, the eyes being near their points. They are passed through the velum about a quarter of an inch from its free edge and towards it, and through two-thirds of its thickness. Each needle carries a double ligature, the noose of which is caught by a blunt hook, and pulled out into the mouth, while the instrument is withdrawn. A second and smaller ligature is carried through opposite to the first, and by means of this second thread, the first and double one is brought through. By a repetition of this plan, two, three, or more pairs of interrupted suture are made. After the edges have been put together by one of two points, so difficult will be experienced in carrying others through both edges by means of a more curved instrument in a handle, or by the use of a small needle carried in the points of a pair of strong and well-pointed forceps. Before the ligatures are finally secured, the parts being put upon the stretch, an incision should be made on each side towards the alveolar ridge through the anterior surface of the velum. By this method, Mr. Liston feels that the edges may be more easily brought together, and the strain is taken off the threads, so that there is less risk of their tearing their way out by absorption. Mr. Liston terms the operation very liable to failure. (*On Practical Surgery*, p. 472.)

Staphyloplastic.—One modification of it consists in facilitating the approximation of the edges of the fissure to one another, by an incision made along the palate, on each side of the division. The ligatures, arranged in the usual way, will now draw the margins of the fissure together, when, without such incisions, this object would be impracticable. This method is followed by Dieffenbach.

The Indian staphyloplastic consists in raising up a flap of soft parts from the roof of the mouth, and twisting its pedicle round, so that

the flap may be adapted, by means of suture, to the loss of substance in the palate. I do not deem it necessary to enter further into the various plans of repairing deficiencies and apertures in the palate, on *Hippocratic* principles. The mode of proceeding in different cases must be decided by the particular nature of them.

[**PATKILL.** Dr. Mitter, of Philadelphia, has performed *Fischer's* operation for displaced patella with perfect success, and in another case he has replaced the patella by a new method. As this gentleman is about publishing a new work on Surgery, he will furnish the details of these and other operations, for which my limits are inadequate.—*Ratio.*]

[**PERIODITIS.** Inflammation of the periodium. Is sometimes an idiopathic affection excited by cold, or mechanical injuries, constitutes a secondary complaint, produced by various deranged states of the general health, as by rheumatism, scurvy, and the abuse of mercury. In the idiopathic form, the treatment should be antiphlogistic, comprising bleeding, leeches, calomel, saline, aperient, and diaphoretic medicines, and purgatives and frictions. In the chronic stage, blustering, and light tonic alterative medicines, are indicated. If no relief be experienced from these, mercury, or incision down to the bone, has been found to answer. The treatment of perioditis occurring as a symptom of some constitutional disease, differ according to the nature of the original complaint; calomel and opium, Aqueous of potash, with sassafras and colchicum, are sometimes, whose usefulness in such cases is universally known.—*C.*]

[**PESSARY.** *M. E. Chéque* gives the particulars of a case, in which a pessary was met with in the body of an old woman, the broad lower end of which had perforated the rectum, while the upper narrower one had produced ulceration of the vesico-vaginal septum, and entered the bladder. These fourths of the interior of its wider part were filled with a white crystallized concretions, strongly adherent to it, with brownish stercoraceous matter between the large crystallizations. The upper narrower end was incised with a section, of irregular shape but smooth surface, and yellowish colour, composed of uric acid. (See *Jules Chéque*, in *Pathol. Chir.*, p. 100. 4to, Paris, 1833.)—*C.*]

[This case will probably be tried by these American surgeons who so frequently oppose the use of pessaries, as an argument of harmlessness on their side of the question. But such extreme cases prove nothing on either side; except that these instruments, like all others, may be misapplied. In the *Scottish Medical Journal* there is an article by Professor P. F. Evis, protesting against the use of pessaries under any circumstances, and citing numerous medical authorities against their use as useless and mischievous. While in the Philadelphia practice of Midwifery by Dr. Meigs, the reader may see an elaborate argument as to their form, not as a universal remedy for prolapsus uteri, but as a valuable auxiliary in certain cases. Dr. Meigs gives the preference to the globular form, and to the metallic material for these instruments. The primitive and most ancient form was that of the globe, for *Hippocrates* recommended the pessaries previously covered in wine, as a pessary. Dr. Physick, while a pupil of John Hunter, employed a billiard ball of ivory, and the only objection was its weight. He ever afterwards employed the

globular form, but preferred a hollow globe of silver covered with gold. Almost every variety of form and material has been used by different surgeons, and to vary the seat and shape of pessaries in different cases is found indispensable.

Dr. Saml. K. Jennings, of Baltimore, after extensive experience in the treatment of prolapsus and other forms of uterine disease, has recently proposed a new form of pessary, which he thinks is adapted to rectify all the evils ascribed to those instruments, and better fitted to fulfil all the requisite indications. His own description of the instrument is here inserted, so far as is necessary to explain its principles.

"If we duly consider the anatomy of the organs to be supported by a pessary, we cannot fail to perceive, that the instrument, if it shall have good protection to a physiological adaptation, ought to fill the cavity of the vagina without inconvenient distention, either lateral or longitudinal. It should reach about four inches above the os calcum, and should have a neck, by which the entire weight of the organ and instrument may be made to rest upon a bandage or cushion fitted for that purpose. Its upper extremity should occupy the cul-de-sac, filling it above the neck, and present a suitable cavity on its anterior side, into which it shall receive the neck of the womb. This last named adjustment will secure to the uterus the necessary elevation, and to the bodies of the organ an inclination in conformity to its natural angle with the vagina; and the neck, when received into the cavity provided for that purpose, will subserve to keep the instrument in its proper position. On the anterior side of the instrument there should be a sulcus or groove of sufficient capacity to protect the urethra. This groove will also enable the patient at any time, very conveniently, with the end of the forefinger, to ascertain whether the instrument retains its intended position; and it will make a channel for the exit of the secretions.

"A pessary made to correspond to these views, should have its body about three and a half to four inches long. Its shape should be ovate-oblong. Its male part should measure about two inches in length, and from an inch to an inch and a half, or an inch and three-fourths, in some instances two inches and a fourth in breadth. Its lengthened or smaller end should measure about an inch and a half or an inch and three-fourths in length, and three-fourths of an inch or an inch and a quarter, or an inch and a half in breadth. To the small end there should be attached a neck or stem, about an inch and a half in length, having at its lower extremity two circular buttons, seven-eighths of an inch in diameter, and one-fourth of an inch apart, for the purpose of receiving and holding the bandage which is intended to sustain its weight. At the upper or larger end of the ovate part, and on its anterior side, there should be an oval cavity, as large as the size of the instrument will admit. The rotundity of the ovate end, aided by this cavity, will sufficiently fill the cul-de-sac, and compress the neck to resume and retain its natural position and angle; and the neck thus supported by the cavity will in turn prevent any change in the position of the instrument. Its lower or lengthened end should be adapted on its anterior side for the protection of the urethra, and there should be a circular indent in the upper posterior side of the ovate cavity, to make room for the neck."

Dr. Jennings has published a brief treatise on the subject, which explains his peculiar views. In old cases of psoasitis, complicated with more or less retroversion of the uterus, he alleges that this latter displacement is attended with a subacute inflammatory condition of the parts, resulting in adhesions, sometimes extensive and obstinate, corresponding to the extent and time of pre-existing irritation. These adhesions resemble tumors, or excruciations per rectum, by the rigidity of the contractions, and he insists that all attempts to maintain the uterus in situ, even after it is replaced, will be unavailing until these abnormal adhesions and contractions are broken up. The manipulation he recommends for this purpose is performed with the finger in the rectum, making lateral pressure in the necessary extent, and repeating the process at suitable intervals, until the uterus can be elevated to its normal state without pain or inconvenience. Meanwhile he advises general and local depletion, corresponding to the pathological state found to be present.

In the *Am. Jour.* for 1842, Dr. J. P. Meigs, of Virginia, reports a highly interesting case of *Metrorrhagia*, connected with malposition of the uterus, with adhesion of its cervix and os to the corresponding portions of the vagina. — *Revue.*

[*PNEUMOMASIA DOLENS*. A swelling of the lower extremities, the consequence of crural phlebitis. It is mostly seen in pariparous women, but sometimes in other women, who have not been pregnant; and now and then in the male sex. I have had two male patients of this kind; one of them was a soldier, in a military hospital at Cambray, during the war; the other was a man who died in the Queen's Bench Infirmary. In the post mortem examination, the external iliac and other veins were found considerably obstructed. Dr. Davis, of University College, was the first who proved by dissection, that *pneumomastia dolens* depended on inflammation of the iliac and femoral veins. (See *Med. Chir. Trans.*, vol. xii. 1823.) One of his cases occurred in 1817, considerably prior to the examples recorded by M. Bonilhard in 1828. The latter states, however, that Chaussier and Meckel had related still earlier instances of *pneumomastia dolens*, in pariparous women; where the crural veins had been found inflamed and obstructed. (See *Archiv. de Med.*, t. ii. Jan. 1823.) — *C.*]

[*PHYSIOMASIS*. Dr. Ewe, of Georgia, has several times performed the operation for *Physiomas* on the plan proposed by M. Cloquet, making small incisions on each side of the lesion, after having retracted the skin as far as possible. — *Revue.*]

[*PNEUMOTHORAX*; (from *pneuma*, and *thorax*.) An accumulation of air in the sac of the pleura. Air may pass into this situation either from the lung or bronchial tubes, or through the parietes of the chest. An example of the former is afforded by the rupture of the pleura pulmonalis, by the bursting of a tubercular cavity communicating with the bronchial tubes; and an instance of the latter is afforded by the *parietal hernia* consequent to certain penetrating wounds of the chest. Air is also stated by M. Astruc to be sometimes generated within the sac of the pleura. This last occurrence is rare; and Dr. Haughton considers that the doctrine of *pneumothorax* being ever formed by the decomposition of a phlogistic effusion, is by no means satisfactorily proved. (See *Treatise of*

Fract. Abdom., art. *Pneumothorax*.) According to Lassarac, the pleura, in some very uncommon instances, secretes air; and the air so produced is occasionally accompanied by an effusion of serum or purulent fluid. "This variety (Dr. Haughton remarks) has not been decidedly established by the dissection of other patients, and we record its existence merely on his authority, and on that of Astruc, who relates a case of it. (*Chir. Med.*, t. ii. p. 517.) It is, however, this origin was not unquestionably proved." (*Op.* 181.)

In cases of *pneumothorax* produced by the bursting of a tubercular abscess into the pleura, the existence of a large cavity, or even of numerous tubercles, is by no means essential. Dr. Haughton has known *pneumothorax* arise, where the cavity which led to the perforation was smaller than a nut. Astruc and others met with cases, where only five or six tubercles existed in the lung; and Dr. Forcand had one remarkable case, where it followed the bursting of a single tubercle which had been found scarcely larger than the pleura, all the rest of the lung being perfectly free from tubercles. The passage of the contents of the tubercle, and of the air, into the sac of the pleura, which mostly happens on the left side, always leaves on its exit a track of acute phlebitis. If this be not speedily mortal, the effused lymphatics become organized, and form a fibrous membrane, enveloping the whole surface of the compressed lung, as a deposition upon the pleura, which lies under it, of its natural thickness. The lung itself has compressed and flattened against the spinal column and mediastinum; and in cases which have lasted some time, it eventually becomes reduced to about one-fourth of its natural dimensions; and then, if removed, its substance is found to be so condensed as to prevent the appearance of what is termed *cardiac lung*. The perforation, by which the air escapes from the lung into the sac of the pleura during inspiration, becomes permanent; and as for the air itself, if it is discharged by passing into the thorax, it is found to be generally an freedom gas, little different from the atmospheric air, whence it was originally derived. (See Dr. John Darg, in *Med. Trans.* 1824; and Dr. Apjohn, in *Trans. of Assoc. of College of Physicians, Dublin*, vol. v.)

In the majority of cases, the air, although it has a free passage into the sac of the pleura, cannot return into the lung during expiration, owing to the valvular disposition of the bronchi; and if this impediment did not exist, still the air could not return into the lung, because the bronchi are full of air. The fluids in pleura, exactly in the same manner as the value of the bellows prevents the air from going out by the aperture through which it entered. The consequence is, that the air exerts a pressure within the sac, and that such pressure continues to increase so long as the communication remains open. The space occupied by the air is much greater than that occupied by the other fluids; and it seems probable to Dr. Haughton, that the chief part of the pressure must be produced by the air, and not by the other fluid.

This species of *pneumothorax* is almost invariably preceded by the usual symptoms of phthisis, cough, hæmoptoe, emaciation, night sweats, &c. Then, at the moment when the air first invades itself into the sac of the pleura, the patient is sometimes conscious of the occurrence, or has a sensation of swelling

having suddenly given way in the chest. Emphysema, as Dr. Houghton observes, being constantly an accompaniment of this variety of pneumothorax, the symptoms of the latter are necessarily joined with those of the former. Hence the insufficiency of the rational symptoms for the diagnosis. "We find the symptoms of emphysema set down as dyspnoea and pain, (cough and expectoration,) distention on one side, dilatation of the ribs, displacement of the heart, depression of the diaphragm, and hectic fever?" (See Emphysema.) The same catalogue precisely makes up the rational symptoms in pneumothorax.

The dyspnoea and pain which immediately follow the bursting of the tubercle, and the first entrance of air into the sac of the pleura, are nearly simultaneous with the sensation above described; but they are still more constantly present, and therefore (as Dr. Houghton observes) of more value in the diagnosis. Yet pneumothorax has been known to take place without either violent pain, or sudden dyspnoea. (Townsend, in *Trans. of Dublin College*, vol. v.; and Houghton, in *Gallien Journ. of Med. Science*, No. 2.)

The dyspnoea, which usually continues during the whole course of pneumothorax, is more urgent and distressing than that attending chronic emphysema. This is accounted for by the great elasticity and condensation of the air, so that even the greatest expansion of the thorax in inspiration can but very partially overcome its reaction, and therefore dyspnoea, resulting from the compression, is thus less trivially mitigated. (See *Cyclop. of Pract. Med.*, art. *Pneumothorax*.)

Different writers give different accounts of the side on which a patient with pneumothorax prefers to lie. "In emphysema (Dr. Dumas observes) the patients commonly lie on the affected side; and in pneumothorax, on the sound one." (*Ed. Med. Journ.*, No. 28, p. 327.) In relation to this point, Dr. Houghton admits the fact, that, in emphysema, the dyspnoea is caused by the pressure of fluid alone, and that it is chiefly for the purpose of relieving the mediastinum, and opposite lung, of its weight and pressure, that decubitus takes place on the affected side. (See Emphysema.) But, he observes, in pneumothorax, the compression of the internal organs is as complete, if not more so, although caused by air; and, if the weight of even an inconsiderable quantity of fluid should be added to them, already suffering under this great compression, the patient will instinctively obviate this by lying on the affected side. According to Dr. Houghton's experience, this position, *scilicet* prona, is always preferred.

The side where pneumothorax occurs, is but slightly or not at all elevated during inspiration; and, on being measured, generally is found to be larger than the opposite one. But in other disorders, and in emphysema, the intercostal spaces are widened and occasionally protrude beyond the level of the ribs. But the column of the intestines of the side, sometimes noticed in emphysema, is not observed in pneumothorax, although M. Louis and others have remarked an anomalous state of the corresponding arm.

According to Dr. Houghton, less compression seems requisite to produce displacement of the heart and depression of the diaphragm than dilatation of the ribs; for the latter has less effect where the heart has been thrust considerably out of its place, and a sensibly thinner pro-

duced in the corresponding hypochondrium by the depression of the diaphragm.

In addition to the foregoing rational symptoms of pneumothorax, is the tubular distillation, which always speedily follows the escape of air by perforation of the tubercular cavity, and is in fact the fever of pleuritis. If the immediate consequences of it are not fatal, this fever subsides into the hectic of pleuritis, which existed previously to the bursting of the tubercle.

The physical symptoms of pneumothorax are highly deserving of attention. Whenever air and fluid coexist together in the sac of the pleura, if the fluid be shaken strongly, the splash of the liquid against the walls of the thorax is often distinctly heard by the patient, or by any one who places his ear on or near the chest. This sound can only be produced where air and fluid are both present; if either is absent, no splashing sound is heard. The action of carefully shaking the trunk to acquire this information, is termed *excussio*.

One of the positive signs of pneumothorax is a metallic tinkling, or ringing sound, detected with the naked ear, and still better with the stethoscope. It is compared to the sound occasioned by the dropping of a pen into a large wine-glass, or touching gently a concave porcelain vase with a quill. It is audible during coughing, speaking, and sometimes during respiration.

The general result of pneumothorax from perforation of the lung by tubercle, is death. Lember is well known to have believed in the possibility of the cicatrization of tubercular cavities; and hence it has been conceived, that, in this case, a recovery is not absolutely precluded.

The chances of it, however, appear exceedingly poor. Even Leconte himself admits, that the effusion of air cannot exist for any length of time, without giving rise to very severe symptoms, and even death. M. Louis only speaks of the result, with the view of calculating the time which elapses between the period of perforation and death. (*Recherches sur le Phtisie*, p. 823.) Dr. Stokes relates a case, which lasted five months, as the longest at that time on record. (*Trans. of King's and Queen's College*, vol. v.) and Houghton, in *Cyclop. of Pract. Med.*

These circumstances are very discouraging to the performance of any operation for the discharge of the air. Cases will occur, where resection, leeches, nistyles, &c., will fail to prevent the dyspnoea from increasing to such a pitch as to threaten the patient with suffocation. Then the only means of cruetting the patient to live longer, is making a small puncture in the chest. This is mostly followed by great relief, which, however, is only temporary. The failure of dissection is ascribed by Dr. Houghton to the readiness with, in such cases, the false membrane and pleura have to inflame and become gangrenous.

Pneumothorax, from the bursting of an abscess of the lung, is rare; and when it happens, the emphysema is generally circumscribed. Dr. Houghton suggests, that this must have been the case in the examples of recovery recorded by Dr. Archer. (*Trans. of King's and Queen's College*) and Dr. Haysborne. (*Edinb. Med. Journ.*, No. 61, p. 6.)

[POLYPUS. Professor Gibbes, of New York, has published in the *New York Med. Gaz.* (for 1841), a report of a case of polypus uteri, which is removed by cauterization, and which he at-

passed by the grounds of his preference of the knife to the ligature in this disease. An abstract of this valuable paper may be found in the *Amer. Journ.* for 1841.

Dr. John Watson, of New York, has published in the *Amer. Journ.* for 1842, an elaborate paper on the pathology and treatment of polypous tumours of the nasal fossæ, with other observations on tumours, in which the whole subject is illustrated by reports of interesting cases, and which will be found to possess great practical value.

The following case of nasal operation for polypus will be found to possess the merit of originality, and is very creditable to the surgeon, Dr. Meigs, of New York:—

The case was a large fibrous tumour from the nasal cavity of the left side. The operation consisted in making an incision through the soft parts, commencing a little on the nasal side of the internal angular process of the os frontis, and extending downwards to the upper lip, which was divided upon three lines, from the angle of the mouth. Two flaps were then reflected, the internal including the cartilaginous parts of the nose, and the flaps covering the os frontis of the left side; the external laying bare the bone as far as the infra-orbital foramen. The anterior part of the tumour was now somewhat more distinctly seen, and the nasal cavity was further exposed by sawing, vertically, through the os septi as far as the transverse suture, so as to avoid the descending plate of the ethmoid. The superior maxillary bone was now divided in a line from the upper part of this os to a point opposite the second bicuspis tooth, and on a level with the base of the nostrils. Another section was made from the termination of the last, extending horizontally inward towards the corner. The osseous parts comprising the os max., a considerable portion of the superior maxillary bone, and the os sphenoid inferius were then detached. The contents of the tumour were partially separated, but the disease was so extensive, that a part had to be removed through the anterior opening, before the posterior attachments could be liberated. These having been detached, the larger portion of this extensive disease, which passed into the pharynx and completely plugged up the posterior nares, was removed by introducing through the nostril a large curved scissor and forceps, and seizing the mass as it descended into the pharynx. (See *Amer. Journ. of Med. Science*, for January, 1842.)

Dr. John Watson, of New York, has published in the *Amer. Journal* for April, 1842, an essay on polypous tumours of the nasal fossæ, to which I can only refer the reader. It abounds in valuable practical information on this topic.

Dr. Joseph Parich, of Philadelphia, was successful in removing polypus from the posterior nares, which he effected by ligature in female He cases, at the Pennsylvania Hospital.

Professor Ke, of Georgia, reports an operation in the *South. Med. and Surg. Journ.* for 1836, in which he removed a large fibrous polypus from the base of the cranium, after repeated unsuccessful attempts to remove it. The tumour filled the anterior and posterior nares, detached the alaræ, protruded the eye, depressed the entire brain, and tragically deformed the cheek of the right side, and it had projected into the left nostril, while it descended the throat posteriorly, and crossed upon the palate, which had

been partly removed by a previous operation. It was found intimately adhering to the basilar processes of the occipital and sphenoid bones, and to the internal plate of the pterygoid process. This intricate proceeding was completed by the entire removal of the tumour, and the patient recovered with very little deformity of the face, and suffering only from the fissure in the palate which became necessary in the operation, and which failed to unite, though the interrupted suture was employed for the purpose. The operation of staphyloplasty is recommended, as the patient has recovered his health, is an industrious farmer, and since married.

Dr. E. H. Dixon has contrived an instrument for the removal of polypus of the uterus by ligature, which, from its simplicity and adaptation to the purpose, possesses great merit. A paper on the subject, with a report of cases in which it has been successfully used, may be found in the 15th No. of the 22nd vol. of the *Boston Med. and Surg. Journal*.—*Revue.*

[POTRICK. The late Dr. Joseph Parich, of Philadelphia, was remarkably successful in the treatment of Ferrigo or Tinea capitis, and his son, Dr. Isaac Parich, has politely furnished me with his mode of treatment. He shaved the scalp as closely as possible, and then applied an emollient poultice for several days in succession, frequently changing it. He then dressed the whole eruption with lin. stramonii, washing frequently with Castile soap and water. If the cure was slow, he again returned to the poulticing, and afterwards repeated the dressing. His success, both in hospital and private practice, was proverbial, so that he was consulted far and near for this class of disorders. Hence the simplicity of his remedies is worthy of imitation, especially in view of the obstinacy and difficulty of cure in these affections, potential among generalists.—*Revue.*]

[PTYALISM. Dr. Fahnestock has published a paper in the *Amer. Journ. of Med. and Phys. Science*, vol. v., on the efficacy of the ether phlegm as a remedy for ptyalism. He observes, that the medication is too attended to check inordinate and protracted salivations are all of a highly stimulating, astringent, and often corrosive nature, such as ipecac, emetic, alum, nitric acid, &c., which seldom fail to aggravate the sufferings, and create deep-seated irritation. Having seen very glowing and even fatal effects from salivation, and the remedies employed to control it, his attention was directed to the use of the gentle astringents, such as common tea, &c.; and finding much advantage from these, the experiments were extended to articles still milder, as the elm, cassia, and peach; from the latter of which he has derived peculiar benefit, and continues to use it with uniform and unparalleled success. An infusion of the root bark of the root of the true ginseng is a very mild, mucilaginous refrigerant; moderately astringent, cooling and soothing to the irritated surface of the mouth and throat, and can be applied at any stage, and even to children. It acts by allaying and obliterating excitement, sheathing the delicate surfaces, and healing abrasions.

It is highly interesting, however, to distinguish the several species of this, and particularly the variety, which resembles the plums very closely, and is very poisonous.—(See *Burton's Essay* on the *Medical Medicine of the United States*.—*C.*)

[In the *Amer. Journ. of Med. Sciences* for 1835,

Dr. Young, of Chester, published an account of an epidemic pyalism which he witnessed, similar to that previously described by Dr. Cooper of Philadelphia, in the *N. A. Med. and Surg. Jour.* Dr. Joseph Parisk, of Philadelphia, was the first to direct the attention of the profession to this subject. It occurs most frequently among the poor, and was ascribed by him to confined air, impoverished diet, &c. The symptoms are thus described by him: "A severe sore mouth, closely

surrounding mucronal pyalism, even in the solid breath. The cheeks become thickened and glossy, a sleeping alteration soon follows inside the mouth, excessive discharge of saliva, extensive aphthulation, and occasionally fatal. In many cases no mercury or other medicine had been taken. Dr. Parisk succeeded in curing numerous cases by the liberal use of bark, generous diet, and a solution of the sulphate of zinc with honey, as a local application.—*Russell.*"

R.

[RHINOPLASTIC. In 1837, Dr. John Mason Warren, of Boston, performed the first successful case of the Rhinoplastic operation ever published in America. It had been previously attempted, but failed to satisfy either the patient or the surgeon. In 1840, the same surgeon repeated this operation four times, the first on a female by the Indian method, the flap being taken from the forehead, and he effected in this case the restoration of the entire nose. In the second case he employed the Italian or Tullastonian method, the flap being transplanted from the forearm, and this is the first successful case by this method in America. In the third case he restored the alae of the nose by sliding the flap from the cheek, on the edge delineated by the French surgeons, *"antéplastric par glissement du limbe."*

In the fourth instance he again adopted the Italian method for the restoration of the tip and alae of the nose, the flap being taken from over the biceps muscle. At the end of 72 hours, adhesion was sufficient to allow of the separation of the flap, which is the shortest time on record in which the separation has been successfully accomplished. The only surgeons in Europe who have attempted this operation were the famous Tullastonian, and Delpech of Montpellier, and Graefle of Berlin. It was not until the fourteenth day that Graefle, in his first case, separated the nose from the arm, and it was a year before the case was successful. In his second case, the flap was separated at the end of six days. (See *Lalut de Rhinoplastie.*) In this last case of Dr. Warren, the patient was well in two months, and scarcely a trace of the operation was visible. This case has not been before published, but the others are reported at length in the *Boston Med. and Surg. Jour.*, to which I must refer the reader. Sufficient time has now elapsed to judge of the permanency of the success which has crowned these surgical achievements.

At first it has been observed in Dr. Warren's cases, that the sensations in the new nose were referred by the patient to the place from which the skin was borrowed, to the forehead in those cured by the Indian method, and to the arm in the Tullastonian examples, but this method state

of the sensation is not permanent. The pins were used in his first case but the interrupted suture was afterwards preferred, and is found to be fully adequate of retaining the parts in adaptation, and to prevent less hindrance to the desired adhesion. Dr. Warren has thus proved that this operation is safe, and may succeed; but he has constructed a new nose, which is so natural in appearance that no trace of the operation can be discovered, unless the attention is particularly called to the fact. He has thus restored to society and to usefulness both male and female patients, who were exiles by reason of their hideous deformity of countenance. See *Anteplastic.*

Dr. Geo. McClellan, of Philadelphia, has performed the Rhinoplastic operation four times with complete success. He adopted the Indian method. Dr. Gibson of the same city has also repeated this operation eight times successfully since 1837, the date of his first attempt at Rhinoplasty. He has repeatedly performed Laryngotomy and Biopharyngotomy. Dr. Matter, also of Philadelphia, has reported a case of Rhinoplasty, to which Velpeau awards the merit of originality in his work on operative surgery. See *Ann. Jour. Med. Sci.*, No. 43, for 1838. The same surgeon has since repeated this operation in five cases.

Dr. Massey, of Cincinnati, has performed the Rhinoplastic operation in two cases; once by the Indian method, successful, the other by the Italian mode, failed, in consequence of the restlessness of the patient.—*Russell.*

[RIBS. Dr. J. C. Warren, of Boston, has twice excised portions of the ribs in cases of metastasizing, and in both cases successfully. Dr. Valentine Hunt, of New York, has also performed this operation in a similar case with complete success, and Dr. McClellan, of Philadelphia, has removed portions of the ribs four times. In one of these cases Dr. McClellan removed a tumor, the result of spinal irritation, excising portions of several of the ribs, and projecting into the right side, displacing the diaphragm and lungs, and by its pressure very seriously impeding respiration. This formidable operation was completely successful, the tumor weighing thirteen pounds.—*Russell.*

S.

[SILVER, NITRATE OF. (*Lassar Caustic.*) One of the best of the milder caustics. Its utility in stimulating indolent ulcers, and keeping granulations from rising too much, is well

known to every surgeon. Mr. Hunter considers its application in the early stage of a chancre, while absorption of the syphilitic virus may not yet have taken place. He directs the caustic to

be scraped to a point, like a black-lead pencil; every part of the chancre to be touched with it, and the repetition of this process till the last slough thrown off leaves the steel hard and healthy. The plan has been advocated by many other surgeons, in the hope that it may lessen the chance of the constitution becoming affected; and it is occasionally resorted to by those who use mercury, as well as by collops who trust to other means for the cure of the venereal disease.

The important use of the nitrate of silver in the cure of numerous diseases which fall under the care of surgeons, I have noticed in various articles of this work. The late professor Dieffenbach believed that it had greater power than any other escharotic or stimulant in expediting the process of cicatrization. I entertain the same belief. Its efficacy in the relief and cure of many diseases of the eye, may be learned from the explanations given in the articles *Congestio*, *Tart. Ophthalmica*, &c. As an application to this organ, it is used either in solution, or in the form of a lotion, or of the black ointment, containing from ten to twenty grains of the nitrate to each drachm of lard. Some examples of lupus, or old raw fingers, are benefited by the nitrate of silver, and a strong belief of it agrees well with certain obstinate ulcerations, which occur round the roots of the nails of the fingers and toes. The lotion is sometimes applied by means of a camel-hair brush; sometimes by means of lint; sometimes with a syringe; and occasionally by dropping it on the part, as, for instance, the eye.

In an interesting "Essay on the Use of Nitrate of Silver," vol. 2, Sto. Læticæ, 1829, Mr. Hoggabottom notices its influence in exciting inflammatory action. That it "should excite the inflammation of phlegmon, or of a line of inflamed abscesses, arrest the spreading of erysipelas, prevent and modify the formation of pus," (says he,) are facts, I believe, entirely new. In some cases of external inflammation, he finds it sufficient merely to blacken the cuticle; in others, it is necessary to produce a degree of vesication. In some instances, the application has appeared to prevent suppuration; in others, a plainly purifying fluid has been absorbed.

Mr. Hoggabottom throws out a suggestion, that the application may prove useful also in internal inflammation, by isolating prompt vesication over the inflamed part, or even without it. But, for a particular account of its use in phlegmonous inflammation, whitlow, erysipelas, inflammation of the abscesses, wounds, ulcers, burns, and cases of hard painful cicatrix from the latter injuries, I must refer to this gentleman's publication, in which will also be found observations on its employment, in examples of diseased joints, inflammation of the urethra, neuralgia, contracted oses, ulceration of the tongue, eye, and navel of infants, and canas. In University College Hospital, I often employ it as a means of checking the extension of erysipelas, which sometimes will not pass beyond a black line made with it. Its use in stricture, and many of the cases here specified, is further explained in other parts of this Dictionary.—C.]

[Dr. Joseph Parich, of Philadelphia, introduced a new method of applying nitrate of silver to old ulcers. Instead of touching their edges with the caustic, he applied it to the centre of the ulcer, and found the effect more speedy and successful, the healthy action concentrating in the

centre and radiating rapidly to the circumference. In the Pennsylvania Alms House and Hospital this practice is now pursued.—REAGER.]

[SPINA RIFIDA. Dr. Sherwood, of Ryland, removed this disease by cranium with complete success in 1831, and the next year Dr. A. H. Stevens, of New York, cured an aggravated case by a modification of Sir A. Cooper's method, by puncture.—REAGER.]

[STAMMERING. This defective defect, in which there are many sufferers, is one which, whether dependent on physical causes, or, as it is more frequently, belonging to the morale of the individual, is one for which no adequate or universally applicable remedy has ever been discovered, notwithstanding the devotion shown to the subject by many scientific and phrenologic individuals. Now, indeed, was it ever imagined that surgery could have any thing to do with the subject, unless in those very rare cases in which the defect is dependent upon a contraction or congenital shortening of the *lingua lingue*. Professor Dieffenbach, of Berlin, has, however, within the last year devised and executed an operation designed to relieve this defect, which he is led to believe is wholly physical, and depending on a malformation of the tongue, which he is of opinion can be removed by surgery. The operation is truly a formidable one, consisting as it does of carrying its incision through the tongue, near its root, in one of three ways, viz., 1st. The transverse horizontal division of the base of the tongue. 2d. The submucous transverse division of the tongue, leaving the mucous membrane undivided. 3d. The horizontal division, with excision of a wedge-shaped portion of the tongue. He has repeated these several times until he has decided that the last is the only one at all adequate to the removal of the stammer.

Of the formidable nature of this operation, and of its hazards, Dieffenbach seems to be fully aware, for he says, "It can never be performed by any one who has not the temperament of an operator; the lamp-glass must hold all others at a respectful distance. The extent and importance of the operation, the possible danger to life, or loss of the tongue, through a want of skill in the assistants, who may tear it, when so nearly separated, or from mortification or ulceration of its connecting substance—these are contingencies naturally to be feared, and which must be carefully weighed beforehand."

Dr. Smith, in his late *Account Report on Surgery*, before the College of Physicians of Philadelphia, when commenting on this passage, uses language which will elicit a ready response from every discreet and conscientious surgeon.

"And yet, with these 'rational fears' before him, Professor Dieffenbach hesitates not to recommend the operation, and surgeons of eminence in France and England are rash enough to act upon the suggestion, even at the risk of human life. And this, too, when the results of the operation are doubtful, and before sufficient time has elapsed to pronounce with certainty upon them. No account of the operation of Dieffenbach having been performed in this country has reached us, and we hope, for the honor of American surgery, that no respectable operator will attempt it."

The suggestion implied in this operation of Dieffenbach, and the reports of its success which have reached this country, have led to the hope

that, in these cases of stammering which are dependent upon physical malformation of the tongue, if there be such, some operation may yet be devised for their relief. No reputable surgeon in America would hazard his professional character by "cutting badly down through the tongue to its root, and excising from its centre a wedge-shaped portion of that member," in the faint hope of removing a defect in the speech, due for any other purpose, except it were rendered imperative for otherwise those entering the speedy destruction of life. The well-known insensibility of the tongue, its permanency of structure, by reason of which hemorrhages from this member are an irremediable after-dorming, even in slight wounds, the actual causality together with the hazard of infirmities by reason of the proximity of such a wound to the larynx and other adjacent structures; all these and similar dangers should deter any surgeon from so imprudent an operation as that of Dieffenbach. Nevertheless, physical obstructions to the motions of the tongue, when investigated in any case where the cause of stammering, might possibly be remedied by surgery, without putting the life of the patient to hazard. Indeed, I have known the division of the human ligament, in adult years, remove a most painful impediment in the speech, which uselessly depended upon an abnormal state of that chord, which had not been attended to in childhood. I succeeded thus in a gentleman, who has since become a clergyman, and is a fluent speaker. But my inquiries on this subject fully satisfy me that such examples among stammerers are rare; and that in most cases this infirmity is either the result of habit, or of some peculiar mental state, and is very seldom the result of any mere physical cause. The success of numerous professors of the art of curing stammerers, and which has become, with some of them, a source of fame and emolument, goes to confirm this view of the impediment in such cases, for the most popular of these professors have been known to rely upon a species of moral training, together with modifying the habits of the patient with respect to the manner of giving utterance to vocal sounds, including attention to the petiolities of respiration. Such physiological and metaphysical expositions of the causes of the defect having been intelligibly explained to the stammerer, a very few practical lessons in elocution have removed from his mind the fallacious idea of its being a physical difficulty, and therefore incurable. And so soon as the stammerer acquired confidence in the ability of his teacher to cure the defect, it has been found that improvement immediately becomes manifest, proving that it is the mental state upon which the difficulty mainly depends.

Some surgeons, who have been deceived by stammerers, who have been desirous to submit to the operation, have devised and performed other and minor incisions in the tongue, and in a few instances the results have been temporarily desirable. These operations are for the most part free from danger, and have been repeated in this country by numerous surgeons. Pioneers Mott and Pithoon, at the Clinique of New York University, and Professor Barker, at that of the College of Physicians and Surgeons, have especially divided the genio-hyoglossus muscles, either by the knife or scalpel, cutting closely to the symphysis of the lower jaw,

when there is very little hemorrhage, and no troublesome consequences need be dreaded. The mouth being washed out with cold water, the hemorrhage ceases. In many of these cases the patients, who could neither read nor speak without a painful and laborious impediment, are so much benefited, that the instant after the incision they will read or speak with a fluency scarcely credible, and they will leave the operating room clattering away with freedom, which inspires a confident hope of entire relief. A single hour, however, too often dissipates the delusion, and they find themselves as bad as ever.

In these cases it is obvious that it is the result of an, as the French Physiologists are wont to say, and the operation, which benefits the patient. Dr. Mott became so convinced of this that he contented himself with simply scarifying the mucous membrane of the tongue, and he found the same temporary improvement as in the cases where he divided the muscles of the tongue. Subsequently he performed acupuncturation, as originally proposed and practiced by Dr. Wm. Leane, of this city, by passing two or more needles entirely through the tongue, and withdrawing them after a few minutes, and the improvement in the speech of the patients was rapid and instantaneous; for, like the rest, the impediment returned, and similar results followed the repetition of acupuncturation a second and third time, which was often decried by the patients. Many of these cases I have seen, and these several operations may either of them possibly succeed, if the patients could be prepared to abide in them with absolute constancy, and their confidence remain unshaken afterwards. This may be the secret of Dieffenbach's success, for to induce a patient to submit to his terrible incision, and enter its attendant dangers, very positive assurances of cure must be given; and if a patient should perchance escape the alarming hemorrhage and inflammation, it would be reasonable to conclude that he would never willingly stammer again, if it would subject him to a repetition of the operation. Those instances in which the defect is dependent upon mental or moral causes, might possibly be cured by the powerful impression made upon the nervous system, which we know has broken up other morbid states perpetuated by habit. I cannot learn, however, that in this country any surgical operation upon the tongue has resulted in permanent benefit.

Dr. Alfred C. Post, of New York, was the first surgeon in America who performed the operation for the cure of stammering, by dividing the genio-hyoglossus muscles near their origin. The operation was performed on the 21st May, 1841. Doctor Post has published an account of it in an Appendix to his "Observations on Strabismus."

Dr. Mott, of Philadelphia, has repeatedly tried the various operations for stammering, including myotomy, acupuncturation, and electro-puncture, &c., but without the least benefit, except in those few cases in which there was a positive laceration. In these, myotomy has been useful.

Dr. Parson, of the same city, has met with ten cases of true muscular tongue-tie, and in these the division of the genio-hyoglossus muscle has been useful in relieving the defect, but in all other cases, surgery has failed to afford benefit.

Dr. Deimold, of New York, having observed, in practicing tracheotomy, the immediate though temporary relaxation of the constricted muscles, on the introduction of the knife, was led to substitute incision of the tongue, instead of the division of the genio-hyo-glossal muscles, as practiced for stammering. He informs that the patients relieved for the moment by his method, very soon relapse and are as bad stammerers as ever. But he is nevertheless of opinion that a frequent repetition of this entirely bloodless, though sometimes very painful operation, will eventually be found to effect a complete cure. — *Revue.*

[STAPHYLOPLASTY. Dr. J. C. Warren has performed this operation five times since 1820, the date of his first case, and is as yet unbroken completely successful. He claims to be the inventor of the needle with a movable point, which he employs in these cases.

His son, Dr. John Mason Warren, has operated upon ten cases of fissure, demanding the staphyloplastic operation. In most of them, the fissure existed in both hard and soft palate, extending to the alveolar process, and in one case of a woman thirty years of age, through the jaw and lip. With one exception, all these cases have succeeded to greater or less extent. Where an operation in the hard palate has preceded after the operation, it has been closed by a gold plate.

Dr. Warren's method has been to dissect off the mucous membrane from the hard palate on either side, and stretch this across the fissure, and then unite the edges by sutures. His success has been equalled in such examples, for surgical authorities all deny that union even of the soft palate can be effected, when the fissure of the hard palate exceeds an inch. All Dr. Warren's cases disprove this opinion, and his operation may be regarded as peculiar to himself. (*See Staphyloplasty.*)

Dr. A. H. Stevens, of New York, was the second surgeon in America who performed the operation of staphyloplasty, which he did in 1826, and it will be found mentioned in the *N. A. Med. and Surg. Journal*, by Dr. Hodge, who was present, and witnessed its success.

Dr. Geo. McClellan, of Philadelphia, operated successfully as early as 1825, and has since performed it in two cases of congenital cleft palate, and seven cases of fissures resulting from disease.

Dr. Gibson, of Philadelphia, has been very successful in this operation, and has constructed very ingenious instruments for staphyloplasty, which he has found to possess to afford great facilities to the surgeon, but for the details of his experience I must refer to the last edition of his *Instruments and practice of Surgery*.

Dr. Metcalf, of Virginia, has published an interesting memoir on staphyloplasty in the *American Journal* for 1828, and he therein describes his invention of an instrument for the purpose, which he has frequently used since 1820.

Dr. N. R. Smith, of Baltimore, has performed the operation four times, and is ten instances with entire success; and Dr. Ponsard, of Philadelphia, has operated twice with the like result.

Dr. Sherry, of Cincinnati, has had complete success in three cases, and partial success in a fourth.

Dr. Alexander E. Bruck, of New York, has published a memoir on staphyloplasty, with

cases, and a description of the instruments requisite for the operation. This surgeon has distinguished himself in this department by the number and success of his operations, and his paper on the subject will be found in *some extraordinary merit*. Dr. Hensck, after the operation of Staphyloplasty, directs his patients to swallow mucilaginous drinks and eat soft food, and finds that the parts constricted are not so far from disunited, but, on the contrary, the swelling effect of frequently moistening the wound, greatly moderates the inflammation. He maintains that the natural tendency of the cleft palate is to approximate the edges to the act of deglutition, instead of to put the tension on the stretch, as is generally supposed. Hence this approximation of the edges to the fissure is the act of healing, which was observed by Mr. Ross, and first suggested the idea of uniting them by suture, and the same natural tendency exists after the operation as before, and hence there is less danger of the suture cutting than, unless cut, if incised by frequent deglutition of fluids.

The late Dr. George Babes, of New York, published a work in 1855, upon Cleft Palate, and proposed instruments of his own invention for its cure. He had operated by staphyloplasty with success in a number of cases, and in the case of his youngest child, had attained a high reputation as a surgeon in New York.

Dr. Mott has had great success with this operation in numerous cases, and his assistant, Dr. Carnahan, of New York, has also operated with success.

Dr. Munro, of Philadelphia, has performed staphyloplasty twelve times, and in the *Amer. Journ. of Med. Surg.*, No. 3, new series, he has published a valuable paper on the subject, describing his instrument, and rendering this operation more simple and easy of performance than by the ordinary method. — *Brux.*

[STETHOSCOPE. (*Greek $\sigma\theta\epsilon\sigma$, push, and $\sigma\kappa\omicron\pi\omicron\varsigma$, explore.)* An instrument consisting of a cylinder, originally employed by Laennec, to elucidate the diagnosis of certain diseases of the chest, but now adapted to throw light on the nature of many other cases. (*See Auscultation.*) — A very few words suffice to state (as Dr. Forbes observes) in what way the stethoscope becomes, in the hands of an expert assessor, the means of an accurate diagnosis. By it we learn, that the motions of the lungs and heart, in a state of health, produce certain determinate sounds in certain parts of the chest; and that these sounds are modified in various determinate ways, and certain other determinate sounds superadded in states of disease. By the study of the symptoms during life, by dissection after death, and by considering the principles of the generation of sound, we are able to ascertain, as cause and effect, particular forms of disease with particular sounds; hence, the indications of the stethoscope, in certain diseases, become positive physical signs of these diseases." (*Cyclopaedia of Pract. Med., and Association*) — *C.*

[STRABISMUS. The success of tracheotomy in the removal of club-foot, by Dr. Steiner, in Germany, and Dr. Denoual in America, led both these gentlemen to suggest the practicability of curing strabismus by the section of the constricted muscles upon which it has been long known to depend.

Mr. Anthony White, of London, demonstrated

its practicality by numerous experiments on inferior animals. But the merit of having first operated for strabismus in the human subject is due to Professor Dieffenbach, of Berlin, which he did successfully in October, 1829.

The following year, hundreds of cases flocked to him from almost every part of the continent, and his success seems to have been commensurate with his opportunities; and in both respects he has probably exceeded any other surgeon in the world. His cases varied from children of five years old to adults of forty, and since his earliest publication on the subject, the operation has been repeated in almost every part of the world, and, for the most part, with gratifying results. Exceptions, it is true, have occurred, in which the deformity has not been removed, and in some cases violent inflammation has followed the operation, disfiguring the patient, and even destroying the eye. In most examples of its failure, however, it will be found that there has been either a lack of discrimination in the adaptation of the operation to the particular variety of strabismus, or a criminal ignorance or surcery on the part of the operator. This must be obvious, when we learn that no such results have followed in any single case of Dieffenbach, notwithstanding they already number some thousands, nor indeed have any such lamentable failures been witnessed among the eminent members of the surgical profession in our own and other countries. Such men have been in the habit of repeating this operation more frequently than any other which deserves the name of surgical, seeing that the number of cases is found far to exceed any estimate heretofore entertained; and no disastrous results have followed, so far as I can learn, from extensive correspondence with those who have extensively practised it, even in a single example. That men who are mere operators, not surgeons, and who aspire to the popular cognomen of oculists, such as that which ignorant pretenders as oculists are wont to assume, should be imprudently mislead to the eye by attempting even this simple operation for the cure of strabismus, is probable and even certain. For the acknowledged simplicity of the operation is such, that those pretenders may occasionally succeed in favourable examples of the deformity, while the patient in such cases experiences a happy cure, rather than a cure. But as they are incompetent to discriminate between the essentially different varieties of strabismus, depending as it often does on the contraction of entirely different muscles, and requiring an essentially different operation from the ordinary one in many cases; and as such men are incapable of detecting and appreciating the numerous complications of the deformity so often present, it would be marvellous indeed, if in such hands any operation should often succeed. Because the operation is simple, every singleton in the fraternity has felt as likely to undertake it, unless his failure he has had the temerity to deny the operation, and quote his own experience in order to bring it into disrepute, thus exposing the cause due to his own ignorance.

Professor Gibson's sentiments on this subject, as well as the estimate that distinguished surgeon places upon the operation, are so well expressed in the last edition of his *Institutes of Surgery*, that I here transcribe them. Speaking of the mischiefs which have occasionally followed awkward attempts in this department, he

says: "These deplorable results are to be traced, no doubt, to the pusillitas with which many physicians are affected in performing such operations as are considered easy, or managed with a medium of skill: so that persons totally incompetent, are too often tempted to such enterprises, at what they consider within their reach, and are only consumed by repeated failures, that they have no room for such exploits. The observation applies not to strabismus only, for I well remember, when liberty was first discussed, how eagerly every eye in Europe and this country, and even common instrument-makers out of the profession, jumped at the opportunity of displaying their skill; men who never would have dreamed of performing lithotomy or hernia, and whose modest flights never extended beyond the most insignificant feats of minor surgery." "The time will come, then," adds Professor Gibson, "that candour, when the operation for strabismus will be considered sufficiently delicate and difficult to be worthy the attention of scientific and practical surgeons, and to be trusted to their care, instead of being placed, as it is at this moment, in the hands of untaught surgical traders and quacks, whose imposition on the public are bolstered up by patients and patients, about as ignorant in such matters as the so-called operators themselves."

In the same valuable work will be found a communication from the eminent British surgeon, Sir Charles Bell, whose lamented death has so recently thrown a gloom over his numerous admirers all over the world whose professional merit is estimated. This paper is fully entitled by Dr. Gibson, "An interesting Essay on the Philosophy of Strabismus." It may possibly be regarded as one among the latest professional productions of his noble life, and for its philosophical accuracy and practical importance, it is worthy of being perpetuated by being placed in the Institutes of Surgery. When Mr. Cooper's last edition was issued from the press, no one in England had heard of Dieffenbach's success; nor, indeed, had this great operation for strabismus been then introduced even in Germany. Hence to mention whatever is made of this new illustration of the benefits surgery is conferring upon mankind.

It appears from the Institutes of Surgery, that Professor Gibson attempted the cure of strabismus by dividing the recti muscles of the eye, precisely as now practised some twenty years since in Baltimore. Soon after he repeated it unsuccessfully in Philadelphia in several cases, and was induced to abandon it by the unfavorable opinions expressed on the operation by Dr. Physick. He, however, calculated the propriety of the operation upon the case many years since, and Dr. A. E. Howard, of New York, then one of his pupils, distinctly reflects Dr. Gibson's expressions of confidence, that the operation would ultimately succeed.

In America this operation for strabismus has become very common, and thus far the cases have been for the most part successful. Sufficient time has scarcely elapsed, however, in any of them, to decide positively whether the deformity will be permanently relieved, and whether the fears which have been expressed of the effect upon the ultimate action of the other muscles of the eye, may or may not be well founded. Some few instances have been reported, in which the division of the internal rectus

has produced a tendency to erosion of the globe under the action of the antagonist muscle, long after the immediate effects of the operation have ceased. If these facts should be realized, it would be a sad result; but no evidence has yet appeared in this country which would seem to render it probable. On the contrary, in a great multitude of cases, in which this operation has been performed in America, I have not heard of one in which, thus far, either the surgeon or the patient has had any cause to regret it; unless in such instances of failure as were justly ascribable to the ignorance of the more operators into whose hands the patients were unfortunately enough to fall.

Dr. Willard Parker, of New York, claims to be the first surgeon in America who performed this operation, which he did in August, 1840, and with success. Dr. Delafield, of New York; Dr. Becking, of Arkansas; and Dr. Gross, of Kentucky, soon after repeated it. I regret that I am compelled for want of room, else I should deem it due to Dr. A. C. Post to extract from his work on this subject a portion of the excellent practical remarks with which it abounds. And for the same reason I am prohibited from doing more than to refer the reader to Dr. Gross's valuable paper on Strabismus, published in the *Western Journal of Medicine and Surgery*, for 1842, abridging, so it does, in discriminating criticism upon popular errors on the subject, and furnishing the best statistics on the subject anywhere to be found. Dr. E. H. Dixon, of New York, has also published in the 16th vol. of the *Boston Med. and Surg. Journal*, two papers on the subject, which are numerous and practical. The experience and success of this surgeon entitle his opinions to respect, but I have space only to make this reference. As, however, Dr. John B. Dix, of Boston, has, in addition to extensive experience in this operation, introduced a method of performing it by subconjunctival section of the muscle, I conclude this article by inserting a brief paper from this gentleman, which, in justice to him, I cannot feel at liberty to abridge.

"The operation of dividing the recti muscles for strabismus, as depicted by Dieffenbach, was performed by me for the first time, Sept. 5th, 1840. I have since that time operated on 218 eyes of 116 persons, in 42 cases both eyes being operated on. In 14 the strabismus was divergent, in the remainder convergent.

"With regard to the success of the operation, there is great difficulty in giving a correct statistical reply. In very many cases the position of the eye operated on is not permanently decided for eight months, and the relative position of the two eyes may not be for twelve; while more than two-thirds of the subjects reside out of the city, and are last sight of in a few weeks after the operation."

"If by success is meant an improvement in the position of the eye, a lessening of the squint, every case has been successful. But if by success is meant perfect symmetry in the contour, correctness in the position, and correspondence in the movement of both eyes in every direction, that is, that the eyes shall be in every respect as if they had never existed, success is rare. But, although, according to this rigid standard, it is rarely found, either among my own patients, or those of other operators, which have fallen under my observations, the result is in a very large proportion of cases an successful

find, that to an ordinary observer there is no evidence of a squint, or other defect in the eye. Such, I should say, is the result in three-fourths of the cases; while in the remaining fourth, either the squint is not wholly removed, or the eye acquires a slight inclination in the opposite direction, or else, the position of the eye being good, there is an apparent enlargement of it, rendering it unlike its fellow; or there may be at the inner canthus an unusual gap or depression, owing to the retraction of the conjunctival fold. The difficulty of deriving what shall be considered a perfectly successful result, or, as it is popularly termed, a cure of squinting, has been alluded to, and I have been careful in the above statement of the result of my own operations not to exaggerate their success, but would say, in justice to myself, that if these eyes only had been taken into the account, which have been operated on for the last seven months, the proportion of imperfect results would be much less, in consequence of adopting a mode of operating different from any hitherto proposed.

"If the first step, in the usual method of operating, is to make a midway between the cornea and inner canthus, a long vertical opening is the consequence, by the subsequent retraction of which the conjunctival fold may sink back, causing an abrupt indentation at the inner canthus, and giving to the eye on this side the appearance of a globe lying in the orbit, but detached from it; the eye may project, appearing unnaturally large; or it may incline outward, or too or even all of these conditions may result.

"The subconjunctival division of the muscle, according to the method of M. Guerin, where it is practicable, prevents or materially diminishes these liabilities, and is performed as follows: "The lids being secured, and the patient in a recumbent position, the eye is turned and kept steady by means of a double hook inserted into the sclerina, and an opening is made through the conjunctiva, and the investing sheath of fascia of the muscle at its lower margin. M. Guerin's knife is now to be passed between the sclerotic and the tendon of the muscle, until it is fairly inserted, when the edge is to be turned outward against the tendon, which sometimes parts with a faint noise. This is similar to the operation of tenotomy in other parts of the body, but in its application to the muscles of the eye is often objectionable; though it may be adopted without difficulty, when the insertion is slight, the globe prominent, and the patient an adult of sufficient firmness to hold the eye covered with his little and from the double hook. In order to give to the muscle the degree of tension necessary for the division of its tendon, by simply turning the edge of the knife against it, the double hook must be applied with a force, which, independently of the pain it occasions, might be, though I am not aware that it ever has been, harmful to the internal texture of the globe, while, from the length of the blade and the rolling of the globe upward, which is prevented only in part by the outward traction with the double hook, the usual motion of cutting is impossible to any useful extent. Unless the curvature of the blade very nearly suits the convexity of the globe, where the division is to be made, as the knife is pressed outward, one portion of the blade may be cutting the conjunctiva before the section of the tendon is thoroughly accomplished. And if it be expedient, as it

very decided cases of squint it is, to divide the muscle posteriorly to its tendon, these difficulties are enhanced. But the more numerous cases of decided squint are precisely those in which it is most important to keep the conjunctiva whole, inasmuch as the greater the squint, the greater the liability to projection of the globe and a gap at the inner canthus.

"I have, therefore, adopted the following method, as far more convenient and effective, and less painful. The patient is sitting with the head inclined slightly backward upon the neck, who raises the upper lid, and the eye is everted as far as possible by a voluntary effort. A horizontal slit is made, either with a knife or scissors, just above the upper edge of the muscle, through not only the conjunctiva, but the fibro-cellular investment of the muscle. Through this opening the blunt hook is passed between the muscle and tendon and the sclerotic, and carrying it fully down, the lower margin of the muscle will be certainly indicated by the appearance of the end of the hook, concealed by the conjunctiva, in which, at this point, a second horizontal slit, about a line and a half in length, is made. Through this lower slit the section of the muscle on its tendon is made from below upward, with a pair of slightly curved scissors, one blade passing between the conjunctiva and the muscle, and the other between the muscle and the sclerotic; the muscle being at the same time raised a little from the globe, and effectually prevented from rolling upward by the blunt probe or hook, which has been inserted under it from above downward, and is held in the left hand of the operator while he uses the scissors in the right. The section of the muscle is known to be complete, when there is full evertion of the globe, only a strip of conjunctiva; but it may be still further verified by holding this position of conjunctiva aside, before the hook is withdrawn, so that the sclerotic may be seen or felt. The horizontal openings in the conjunctiva will, at some cases, be found to afford a convenient opportunity of making a free section of indurated and contracted cellular or fibrous tissue, both above and below, a proceeding which, in cases of long-standing, is often required; and from the direction of the slits, their edges are brought more nearly in apposition, the greater change which has taken place in the position of the globe.

"I am fully aware that little credit attaches to those who, following in the track of a great discoverer, strive to appropriate to themselves, by trifling or imaginary improvements, a portion of his reputation, and would by no means be understood to say, that very perfect results have not been obtained in the manner originally directed by Professor Dieffenbach, or that M. Guerin's operation is in all cases impracticable or unsuccessful; but only to express my conviction, that by preserving the integrity of the conjunctiva between the cornea and inner canthus, very important objections to the operation are obviated, and to point out a method by which this may be most easily and thoroughly effected in decided cases. And I am the more convinced that some modification of M. Guerin's method was needed to render it consequently applicable in decided cases, by the fact that I have searched the foreign journals in vain for evidence of the adoption of the subconjunctival operation by those gentlemen who have made the most valuable communications on the subject of Strabismus.

"In one respect only, the subconjunctival has no advantage over the usual methods. Some cases will occur, in which the division of the internal tendon, as far back as possible, is not followed by a sufficient change in the position of the globe, owing either to the joint action of the oblique muscles, or the inner fibres of the superior and inferior recti, or to the influence of the union vaginally with the recti. The division of more than one muscle is seldom, perhaps never expedient, as shown as by repeating at intervals of four or six weeks the division of the same muscle, or rather separating its recent adhesions, a straight position will be gradually attained with less projection of the globe.

"When the squint affects both eyes, the two should never be operated on at the same time, and a much longer interval should elapse than is recommended by writers on this subject. Too great haste may result in the eversion of one or both, a result which can be averted only by dividing the opposite muscle at the expense of an increased projection. I now wait six and twelve months before touching the second eye, which, meanwhile, frequently becomes sufficiently straight, and accordingly the proportion of cases in which both are operated on is much less than formerly.

"The above remarks apply to convergent Strabismus.

"In divergent Strabismus the operation may be considered to be almost invariably and completely successful. I have seen in but one case any sensible projection of the eye. It is, therefore, in this form of strabismus, not important to perform the subconjunctival operation in view of the ultimate result, though by preserving the integrity of the conjunctiva the subsequent inflammation, slight under any circumstances, is still less, and no inconvenience is felt from the temporary lacerous growth, which often arises from an extensive vertical section of it."

The following analysis of 50 cases of strabismus has been prepared by Dr. Dix, of Boston, and may serve as indicating the value of the numerical method. It is extracted from his treatise on the subject.

Analysis of 50 cases.

Females	31
Males	19—50
Convergent	48
Divergent	2—50
One eye only squinted and was operated on in	35
Double, that is, requiring the operation on both eyes	14—50

Three cases are supposed to have been congenital, and the squint was observed previous to the eighth year in every case except two.

The causes assigned were as follows, viz.: Fits six, inflammation five, Hooping cough five, Chorea one, Blow ten, Fracture of skull one, Intussusception eleven, Unknown aetiology—Recess.

[STRICTURES IN THE URETHRA. Dr. Alfred C. Post, of New York, has published in the New York Journal for 1880, a series of Hospital Reports on this subject which is of great practical value, but my limits will not allow more than this reference to his paper. In one extremely aggravated case, complicated with fistula in perineo, this gentleman adopted the treat-

ment by ligation, though in most cases he has succeeded by gradual distention.

Professor Dugas, of Georgia, has a paper on the subject of treating strictures by excision in the *Southern Med. and Surg. Jour.*, vol. i, p. 211.

Dr. Allan Goldsmith, of New York, is devoting a large share of attention to the treatment of strictures of the urethra, and has had great success in the employment of iron bougies of a conical shape, upon which he chiefly relies.

Dr. Palmer, of New York, reports in the *New York Gazette*, vol. i, No. 2, 1841, a case illustrating the dangers of employing bougies made of elm bark, which material has been recommended in some of the journals. In this case he was obliged to perform the lateral operation of lithotomy, for the removal of a ball composed of elm bark left in the bladder by the employment of bougies and catheters made of this substance. One such case occurring in a century ought to banish such bougies from practice.—*Review.*

[STRYCHNIA. Its calls, and the extract of nut vomica, have been found useful in paraplegia, anasarca, some forms of deafness, and a few other paralytic affections, from disease or external injury. The anesthetic use of strychnia is noticed in the article ANAESTHETICS. "Strychnia in all its forms, pure or combined," says Mr. A. T. Thomson, "is a powerful excitant, displaying its influence, first by an increasing energy of the whole system; and next chiefly on those tracts of the medulla spinalis, which give origin to the motor nerves. The nerves of sensation, however, are also involved in this action; for, along with the muscular contractions and convulsions which supervene, the surface of the body is so morbidly sensitive, as to be sensible of the slightest hyperæsthesia; even the motion of the air becomes a source of uneasiness, nearly as considerable as in hydrophobic cases." (See *Edin. of Nat. Hist. Med.*, &c., p. 186, edit. 2.)—C.]

[STUMPS. P. G. Van Boome, in 1803, published a valuable work giving an account of the changes which occur in the texture of stumps after amputation, and particularly in the bone. *De la, par in partibus nuda periculis, acutis emulacione, adheſione, necesse sunt* (Lugd. Bat. 1803, 8vo.) In the 18th vol. of the *Med. Côt. Trans.*, Mr. Langstaff has published many interesting remarks on the healthy and morbid condition of stumps. According to his investigations, after the division and organization of lymph in the healing process, "the absorbents remove such superfluous parts of the muscles, as are likely to retard the progress of cicatrization of the integuments. After this period, the nutrient arteries of the potential covering of the divided bone or bones, and the medullary parts, deposit lymph; a medium of cellular tissue is produced, which unites to the organized integumental surface, and these together form a capsule, as a protection to the end of the stump." The absorbents remove the superfluous ossification by the division of the bone; a deposit of coarsen matter takes place round its edges, forming a junction with the new bony substance thrown out by the vessels of the medullary texture; and the absorbents, if not interrupted by a diseased state of the stump, produce a regular rounded appearance of the extremity of the bone, in which merely superfluous are left for the cicatrization of the nutrient arteries, veins, and nerves of the shaft of the bone, with its covering.

"Should the surface of the amputated part not regularly unite by the first intention, or by

the second, and there be inflammation affecting the divided nerves, then a morbid action is established, which occasions the fibres of the stump to ulcerate or mortify; frequently causing a protrusion of the extremity of the bone to process, which occasionally becomes carious, and should be taken off." In other instances, osseous deposits take place under the edges of the skin, in various degrees amounting to exostosis; and sometimes a spiculum of bone projects from the stump, generally taking the direction of the artery, vein, and nerves of the limb, which thus become implicated with the bony deposits; and sometimes (says Mr. Langstaff) "I have found a large spiculum of bone, with a very sharp point, taking an oblique direction, and connected with a muscle, occasioning morbid changes in its fibres, and being a source of great suffering to the patient. In all such stumps, I have invariably found the nerves greatly enlarged at their extremities, giving them a glistening appearance, and generally firmly adherent to the surface of the stump, and frequently as risen with spicula of bone." On cutting through these bony extremities of the nerves, Mr. Langstaff did not notice any marks of enlargement of their natural structure, the thickening appearing to have been occasioned wholly by the deposition of lymph, the effect of inflammation in the cellular tissue covering the tendons. Mr. Langstaff gives the particulars of numerous preparations and cases in confirmation of his statements. In amputations, he prefers the flap operation to the circular, cutting obliquely through the integuments, muscles, vessels, and nerves, and taking especial care to preserve a sufficient quantity of skin to cover the end of the bone. He notices the bad consequences of leaving too much muscle in the circular operation, in impeding the adhesive process. "If," says he, "in performing the flap operation, a sufficient quantity of skin is not preserved to cover the stump, and the ends of the nerves are likely to be included, while cicatrization is going on, I should have to lament its shortening them by cutting off a portion of each."

The frequent necessity, however, for cutting the large nerves twice, is considered by many surgeons—as which number I wish to be included—as one of the principal objections to flap amputations, more especially of the arm. Thus Sir Charles Bell observes, "Of all the conditions to which man is subject, there is no state of suffering more severe than that produced by the engagement of a nerve in a stump; and therefore I say, that it is most important that the nerve should be directly divided across, and not obliquely torn out. You cannot seem the effect unless you make a free and decided division of the muscles. When you pierce the limb with a great cutting knife, and put it close as the bone, and draw it out obliquely, to make the flap, you cut the nerve longer than the other parts. The nerve is firm, but very elastic; it is not so easily cut through as muscles. Hence change, it goes before the edge of the knife; and, if you look carefully to an amputation performed in this way, you will find that the nerve hangs out, that it becomes necessary to draw it out, and cut it again. What do you say to cutting the nerve a second time, by way of proof that this operation is attended with less pain?" (See *Leed. Med. Gaz.*, vol. xv, p. 35.) In post mortem examinations, Mollin and Morgagni long ago found the ends of nerves, which had been cut through, enlarged. Lower and An-

remain noticed the same occurrence in animals, and Prochaska gave an instructive description of such a case.

In Van Hoesen's work are excellent representations of this condition of the nerves, as well as of the enormous deposition at the end of the bones of stumps, and of nerves in various degrees and stages. In Forrier's *Clin.-Kupferstich*, pl. 113, the same things are represented, accompanied by an account of two preparations of stumps, preserved in the museum of the University of Bonn by Professor Mayer, the particulars of which merit the attention of all who are investigating the present subject. Cuvillier has published a representation of a shoulder-stump, after an amputation performed many years previously by Larrey. The changes in the muscles and ends of the vessels are carefully drawn and explained, as well as the ganglionic enlargement of the nerves. (*Anat. Pathol.*, t. i. livr. vi. p. 3.—Paris, 1829, 3s. fol.)

In University College Museum is preserved a stump, which, in consequence of bleeding, had been opened on the first night succeeding amputation. Looked over some days; the bone protruded to the extent of an inch; and in six weeks the case ended fatally. The extremity of the sciatic nerve is seen enlarged; and conformed to the cicatrix.

When the severe neurogic affection of a stump, sometimes attended with convulsive twitches, is dependent upon the badness enlargement of the end of a nerve, it may sometimes be cured by the repetition of amputation, or even by the mere excision of the extremity of the nerve. The latter operation, I think, with Mr. Mayo, is to be preferred, if the symptoms are clearly attributable to an affection of one nerve. (*Revue Pathologique*, p. 139.) In support of this advice, Mr. Mayo gives an interesting example of the success of the practice. He likewise adds the particulars of a case, in which the source of the painful affection of the stump was not confined to the cut extremity of the nerve. A second amputation had been performed. "On examining the amputated part, the sciatic nerve and the saphenous nerve were found to terminate in large callous bulbs. In the second operation, care was taken to draw out and remove a considerable portion of the sciatic nerve, which, extracting, lay well covered among the muscles. Nevertheless, when the stump had nearly healed, the old pain again commenced," but was more circumscribed. Mr. Mayo now cut down to the sciatic nerve, where covered by the lower flaps of the gluteus maximus, and divided it. "A portion of it was then removed. The benefit was only temporary. Mr. Mayo suspects that amputation at the hip might cure this patient, though both to recommend this formidable proceeding; and refers to a case in which a neuralgia, which had followed an amputation above the wrist, had returned after a second amputation, but been permanently cured by amputation of the shoulder. Sometimes the relief afforded by excision of the bulb of the nerve is not complete, as we find exemplified in the case under Mr. Palmer, who removed from a stump a portion of the brachial nerve. "The stump is still occasionally agitated by slight spasms, and the nerve, for above two inches above the cicatrix, (as may be perceived by feeling through the integuments,) is still enlarged and very sensitive. Unquestionably the relief afforded has been immense; but I now regret that I did not in the first place remove a

greater length of the nerve, so as completely to exclude the possibility of its being again involved in the new cicatrix." (Palmer, in *Lond. Med. Gaz.*, vol. xvi. p. 230.)

When the soft parts are deficient, and the bone protruded on the face of the stump, various attempts are often made to bring the integuments together by adhesive straps. These misadventures (as Mr. James correctly observes) commonly fail, but are indeed mischievous; for, if the straps are brought over the surface of the bone, then they bind down this thin and brittle covering upon a broad surface, which is sure to dislodge them to some; and, if applied at the sides, although they may bring the edges together, yet they will force the soft parts still more back than the bone. The only remedy for such stumps, according to Mr. James, is to be found in the skilful application of a truss, and a proper position; and these failing, in sawing off the bone higher up. (See *Practical Med.* and *Surgical Trans.*, vol. iii. p. 228.)

Mr. Benjamin Phillips has written some good remarks on inflammation of the medullary membrane succeeding to amputation; one of the most serious, and, as it appears to this gentleman, not the least frequent of the accidents which follow its operation. He from this case that proceeds to the whole thickness of the osseous bone mostly arises. The several stages of the case are well described by Mr. Phillips, as that of simple congestion of the medullary membrane; another, leading to osseous deposits; a third, attended with the formation of pus; and a fourth, with gangrene of the texture in question. Mr. Phillips ascribes the disorder to the violence inflicted upon it by the saw. An anxiety, he observes, is felt to prevent such action of the saw upon the periosteum; "but the action of the instrument upon this membrane would not bring about these formidable consequences, with which such injuries to the medullary membrane are pregnant." He notices the custom, followed in many parts of the continent, of applying a very tight bandage round the stump, for the purpose of preventing the retraction of the muscles. "This system," he states, exists at La Charité in Paris, where the promotion of premature terminations in cases of amputation is very great. Dr. Carswell thinks it probable that this tight bandage does not produce congestion, and a tendency to inflammation of the medullary texture of the osseous bones. (B. Phillips, in *Lond. Med. Gaz.*, vol. xii. p. 188, &c.)

When the end of the femur, tibia, or other bone of a stump, is affected with caries of its whole thickness, and this for some extent, the excision and removal of the sequestrum is the most expeditious means of cure. (C.)

[SUTURES.] For the few operations in which the twisted suture is still retained in practice, the common pin, preserved by Vespasian to that made of steel, silver, or gold, has been generally introduced into this country. This objection to steel, that it soon oxidizes, is not remedied by glazing them, as experience proves. When silver or gold is used, they become too thick when the steel points are applied, and they are not firm enough to act without them. Dr. Eve, who has employed the common pin, informs me that he has known it to remain ten days beneath a varicose vein, and yet continue as bright as ever. Vespasian prefers the common pin in all cases of operations upon the veins, where it is so important to avoid inflammation.

Dr. E. H. Dixon, of New York, has devised a novel form of needles for passing the interrupted suture in deep seated wounds, and adapted also to staphylocraphy. I regret that

my limited space will permit me only to refer to the 25th vol. of the Boston Med. and Surg. Journal for a description of the invention.—*Amnat.*

T.

[TENOTOMY. The name given to the division of tendons for the removal of deformities dependant upon a loss of equilibrium in the antagonism of corresponding muscles, as recently practised by Stromeyer and Dieffenbach, in Germany, and within a few years adopted throughout the surgical world. The divisions which have been divided by surgeons within a few years past for very neck, strabismus, club-foot, and other deformities are very numerous, and I must content myself with a brief catalogue of the muscles whose tendons have been subjected to division in America, referring to the several articles in this Appendix for further and detailed information. The sternocleidomastoides; tendo Achillis; fibula anticus and posterior; peroneus; flexor digitorum profundus; the extensors of the toes; the flexors of the toes; the continuations; the semitendinosus; the gracilis; the sartorius; the adductor longus; the tensor vaginae femoris; the fascia lata; the gluteal fascia; the masseter; the biceps brachii; flexor carpi radialis; flexor carpi ulnaris; palmaris longus; flexor digitorum manus sublimis; flexors of the fingers; pretorius; biceps brachii; gemelli digitorum; rotator internus and externus oculi; superior and inferior rectus; superior and inferior oblique, besides a great variety of the flexor and extensors of the limbs. All these tendons have been divided subcutaneously, a measure which is found not only to make the operation almost bloodless, but which, at the same time, avoids subsequent inflammation, and greatly facilitates recovery. (See WILKINSON, and other examples of orthopedic surgery.)—*Hæzer.*]

[TESTICLE, DISEASES OF THE. Sir Ashley Cooper believes, that the body of the testicle is less prone to disease than the rest of the human body, but acknowledges, that it is often the seat of disease, and that the spermatic cord, and the coats of the testicle, are subject to a great variety of diseases. Among the circumstances which appear to him to offer some explanation of the frequency of diseases of the testicle, are the following: 1. Their position, situation, which renders them very liable to inflammation. 2. For the blood granules, testis, and returns with difficulty by the veins. 3. The exposure to which they are liable from passion, and which, when an admixture of being immediately grafted, leads to an accumulation of sexual secretion, and to a painful and excessive distension of the spermatic tubes, followed by inflammation. 4. The testicles are greatly exposed to blows and pressure. 5. They are frequently involved, secondarily, in consequences of diseases of the urethra and prostatic gland. 6. The changes which the testicle undergoes in old age and at puberty, sometimes being of disease. 7. 8. The liability of the testicle to be prevented, or interrupted, in its descent into the scrotum. This movement, though usually completed before birth, is often delayed for years, and the testicle may thus remain at the lower

part of the abdomen, or in the groin; in which last situation it is much exposed to injury. (See Sir A. Cooper, On the Structure and Diseases of the Testis, part 2, p. 5.)

The diseases in which this organ is concerned, conveniently admit of being referred to four heads: diseases of the testis; of the tunica vaginalis; of the cord; and of the scrotum. The reader will find an account of the three last classes of diseases in the articles HYDROCELE, FLUORESCENCE, SCROTUM, and VASICULITIS, so that these subjects will not require particular notice in this place.

It would perhaps be difficult to cite any department of surgery in which greater improvements have been made, within the last twenty years, than in that which relates to the dissection and more judicious practice adopted with regard to diseases of the testicle. The testis is, that operation, which at one period used to be performed every week, and sometimes two or three times a week in the hospitals of London, is now a comparatively rare proceeding. The same beneficial reform appears, from the testimony of Dupuytren, to have been also made in France, where, he observes, that the love of operating, without any kind of true occasion for the measure, was formerly more conspicuous only exemplified than in cases of enlarged testicles. But, says he, at the present day, about a hundred patients are annually admitted into the Hospital for such diseases, most of whom are cured, and stand in no need of being operated upon. In the majority of instances, Dupuytren ascertained, that the enlargement of the testicles proceeds from external violence, syphilis of long standing, or from scrophulous or some other unfavourable state of the general health; and hence he regards it a rule never to resort to castration, without having first tried, for a full month or six weeks, some method of treatment adapted to the cause of the complaint. (See Dupuytren, in Clin. Chir., t. i. p. 85-88.)

Acute Inflammation of the Testis: Orchitis, (from *orchis*, a testicle,) or *hemorrhoiditis*, as abroad has commonly name for the complaint, more especially when it arises from irritation in the urethra, another excited by gonorrhoea, injections, bougies, or stricture. This last expression being founded, as Sir Ashley Cooper justly observes, upon mistaken pathological principles, it ought to be rejected. When acute inflammation of the testicle shows even sympathy with the urethra, the first symptom is an irritation in the membranous or prostatic portion of that canal, succeeded by tenderness in the spermatic cord, and swelling and pain in the epididymis. The swelling perhaps is generally first noticed in the latter part, the testicle next swells, soon increasing in two or three times its natural size, and becoming so tender that the pressure of the thigh on it can scarcely be endured. Its weight being also increased, it draws the spermatic cord painfully downwards; and, in this state, the patient complains of

held by supporting the part with his hands. The pain is obscure, resembling the suffering caused by squeezing the testicle. The pain and swelling extend along the spermatic cord into the inguinal canal, and great tenderness is experienced in the groin, hip, inner part of the thigh, and especially the knee, in consequence of the origin of the spermatic nerves from the lumbar. "From the communication between the renal and spermatic nerves, with the nerves of the stomach by the solar plexus, and with those of the intestines through the mesenteric plexus, the stomach is affected with nausea, and sometimes escape vomiting," and pain in the intestines and moderate constipation are usually experienced. (See *Astley Cooper, Op. cit.*, part 2, p. 8.)

Although the testicle is sacculated in its capsule, that the edge of the scrotum, or rather, it still retains its originally oval form, being rounded at its fore-part, but somewhat flattened at its sides; and it feels exceedingly hard. The scrotum, the ridge of which are obliterated by the distension, presents a smooth appearance, and is rather thin; natural; and, as scum is effused in its cellular tissue, it often pits or pines. Its veins are quite large and prominent, and, if punctured, bleed very freely. With reference to its original dimensions, the epididymis always feels more than the testicle itself; which Sir Astley Cooper ascribes to the covering of the former part being less compact. The epididymis remains also longer swollen than the testicle, the glands major and minor being more enlarged than its body, and the swelling of the first generally very perceptible in front of the spermatic cord. The pressure made by the tendon of the external oblique on the swollen cord is the occasion of severe pain, which sometimes undergoes severe exacerbations from spasm of the cruminal.

During the violence of the inflammation, the constitution is often greatly disturbed; the tongue becoming furred, the pulse quick and hard, the skin hot, the bowels confined, and blood taken from the arm, presenting a buffy and coagulated appearance. It is an observation, made by Sir Astley Cooper, that when acute inflammation of the testicle arises from sympathy with the urethra, it rarely proceeds to suppuration, but when it is the effect of a blow, or of vicissitudes of temperature, suppuration sometimes, though not frequently, follows; and then all the symptoms are aggravated, and suppuration added to those already described. In fact, the purulent matter being confined by the fibrous covering of the albuginea, a texture that adheres with difficulty, much time elapses before the abscess bursts; and when this happens, several openings and sinuses are frequently formed, which discharge both pus and seminal fluid, and are difficult to heal. (See *Astley Cooper, Op. cit.*, p. 10—12.)

A case attended a soldier, with acute inflammation of the testicle, in the Military Hospital of Cuscutary, who experienced so much pain in the abdomen on the fifth day of the attack, accompanied by vast swelling of the cord, almost incessant vomiting, complete and obstinate stoppage of the stool, and severe constitutional disturbance, that a suspicion of hernia was raised. The absence of tension in the abdomen, the limitation of the pain to one side of the belly, the inability of finding anything like the testicle of its ordinary size below the tumor, so in a horizontal, and the history, which made it im-

possible that the case could be a congenital hernia, were circumstances, which prevented an erroneous view of the complaint from being adopted. "But, (as Sir Astley Cooper observes,) if a hernia had existed on the side by which a blow has been received, and the patient has a swelling attended with exquisite pain, sickness, and vomiting, redness of the scrotum; or even a purple appearance of it, suppuration, of two or three days continuance, with tenderness of the abdomen, then great caution will be required in forming a judgment of its nature, and in determining on its treatment. It will be best to give a purgative injection immediately, as well as an aperient medicine; and free evacuation from the intestines will determine the question. The swelling will be harder than hernia, its form different, and there will be a greater pain in the part." (*Op. cit.*, p. 13.)

With respect to the causes of acute inflammation of the testicle, the greater number of examples of it unquestionably arise from irritation in the urethra, especially its prostatic and membranous portions. In the early stage of gonorrhoea, inflammation of the testis rarely occurs, but between the tenth and twenty-sixth days, it frequently takes place. "Sir Astley Cooper's investigations lead him to believe, that it happens in consequence of the vegetation, and irritation of the seminal ducts, by contagion; and the inflammation extending along the interior of the cat deferent to the testicle." (*Op. cit.*, p. 13.) When inflammation of the testicle comes on in gonorrhoea, the urethral discharge generally stops, or undergoes a considerable diminution, so that it appears to some pathologists as if there were a transference of the inflammation from the urethra to the testicle; a view to which Sir Benjamin Brodie inclines, and which is entirely different from the other, to which I have been alluding. He states, however, that "inflammation of the testicle seems to be sometimes independent of the transference of the inflammation, or of the suppression of the discharge from the urethra; and it must then be attributed to the extension of the inflammation of the urethra, and not determined to the testicle." (See *Lancet, Med. Gaz.*, vol. xii, p. 218.)

By many surgeons, the employment of injections for the cure of gonorrhoea, is regarded as a frequent cause of inflammation of the testicle. If they be used, Sir Astley Cooper is of opinion that the patient should be directed to compress the urethra two inches from its orifice, so as to prevent the fluid from passing beyond that point, and towards the membranous and prostatic portions only.

It is well known to every soldier of experience, that the irritation of the urethra with bougies, or catheters, often brings on inflammation of the testicle; but, according to Sir Astley Cooper's observations, this rarely happens, except when the instrument is pushed beyond three or four inches. Any injury (the size) of the prostatic gland may have the same effect, as a sometimes noticed after lithotomy. "The prostate gland, which seems almost in a constant state of ager, is sometimes accompanied with inflammation of the testis. Inflammation on the neck of the bladder produces this disease; and a calculus in the bladder, pressing upon the neck of the urethra, has been known to occasion it, although it generally produces only a spasm of the urethra muscle. A blow upon the testis is a frequent cause; and, if it be severe, it

produces swelling at the instant." (Sir A. Cooper, *Op. cit.*, p. 18.)

The same distinguished surgeon has remarked, that "a wound of the testis does not produce the pain and inflammatory effects which might be anticipated; for (says he) I have several times known a thick, and even a broad, thrust into its substance. It is followed by a screaming pain, and the patient sometimes vomits; but the wound heals readily, and without suppuration. In one case, however, in which the thorax was twice thrust into a testis, violent inflammation and suppuration succeeded." (*Op. cit.*, p. 19.) The scrotum, not yet descended into the scrotum, they induce from the pressure of a thrust; and give rise to excessive pain, counting, constipation, tenderness in the abdomen, and severe urinate disturbance.

Acute inflammation of the testicle often produces a considerable effusion of serum fluid in the cavity of the tunica vaginalis; but, as the substance of the inflammation, this kind of hydrocele is absorbed. Another effect, noticed by Sir Astley Cooper, is adhesion and thickening of the above membrane, which effects coagulation and in a great while, and may be mistaken for a disorgan of the testis itself. The adhesion of one portion of the tunica vaginalis to the other may be either partial or complete. The epididymis also yields, sometimes at its lower, and sometimes at its upper part. When such swelling is at the lower, it is believed by Sir Astley Cooper to be situated in the cellular tissue of the vas deferens, where it forms its first convolutions; and frequently it does not depend upon any effusion in the interior of the duct, and consequently the fluctuation of the testis continues perfect. When the swelling occupies the upper part of the epididymis, or its globus major, adhesive matter is effused into the cellular tissue, "between the rete vasculum, at their termination in the epididymis, and sometimes a jar, containing a sanguinolent fluid, is found in this part. This portion of the epididymis is more frequently diseased than any other part of it, or the testis; but the result is less important than in other parts, because some of the vasa effluents and venous blood will carry the serum from the testis to the epididymis. The coat vasculosa, after this stage of disease, are thickened, hardened, and of a dark brown color." Sir Astley Cooper possesses also a preparation, in which, after inflammation, a nodule, somewhat larger than a pea, was seated amidst the seminiferous tubes, surrounded by an exceedingly vascular surface. In general (says he) I observe, that where there are marks of inflammation upon the tubes of the testis, such as thickening, the substance of the gland itself is changed, the septa are much more apparent than usual, the number of the seminiferous tubes is diminished, and their size so reduced, that many are converted from tubes into mere cords. (Sir Astley Cooper, *Op. cit.*, p. 21.)

The actual condition after inflammation of the testicle, is described by Sir Benjamin Brodie as depending upon effusion of lymph into the interstices of the tubular structure, and as not producing any permanent injury of the function of the organ. In six or twelve months, the hardness disappears; "but," he adds, "there are a few cases, in which the inflammation is so severe, as actually to injure some portion of the glandular structure. I examined the body of a gentleman, who had had inflammation of the testicle

from a gonorrhoea twenty years before. The testicle, which had been inflamed, was then three times smaller than the other, and a part of it remained considerably indurated. I knew these facts previously, and I was curious to examine the state of the testicle by dissection. On taking a section of it, I found that about two thirds of the tubular testis remained in their natural condition, while the remainder had become converted into a white substance, having the appearance, but not the fibrous structure, of ligament." (*See Lond. Med. Gaz.*, vol. xlii, p. 218.)

Atrophy, or a wasting away of the testicle, which is an occasional consequence of inflammation of it, is observed by Sir Astley Cooper to take place more frequently at puberty than any other age. A person receives a blow on the part, or the testicle inflames spontaneously, or, more rarely, the atrophy follows some hæmorrhage from gonorrhoea. The change consists in an absorption of the whole of the glandular structure, the tunica vaginalis being left adherent to the tunica albuginea, with the septa within the latter. In a wasted testicle at St. Thomas's Hospital, quickly dissected in the vas deferens only about half way between the abdominal ring and the epididymis. (Sir Astley Cooper, *Op. cit.*, p. 21.) A patient with acute inflammation of the testicle should wear a suspensory, and keep himself quiet on a sofa, or even in bed, in the recumbent position. Leeches should be applied to the scrotum, and, if the local and general symptoms be severe, it may be necessary to take blood from the arm, or even the legs by cupping. When leeches cannot be obtained, the surgeon may penetrate three or four veins of the scrotum, with the point of the lancet introduced transversely with respect to these vessels, which will then bleed freely, more especially if the parts be placed in warm water.

The recumbent position does not obviate the necessity for supporting the testicle with a suspensory bandage, or bandage, and, as Sir Astley Cooper remarks, the inflamed part should thus be brought towards the abdomen, and not suffered to fall between the thighs, which would destroy the salutary influence of the recumbent posture. The suspensory bandage should have four tapes: two in front and two behind. The two anterior are carried to the hips, which they cross, and are tied on the femur of the abdomen; whilst the two behind ought to be brought up to the perineum of the groin upon each side, and should be fastened to those which crossed the abdomen. Thus a good support is given; but if the hinder tapes are carried between the thighs to the hips, as they usually are, the testicles are partially drawn back, rather than supported." (Sir Astley Cooper, *Op. cit.*, p. 25.) When the patient has not a regular suspensory bandage, he may support the part very well with a handkerchief, which may be fastened at each end to another handkerchief, or hand, placed round the loins, or a bandage, which may be "fastened in a triangular form, and a piece of tape attached to the middle of its base, and carried between the thighs to the back, where two of the ends of the handkerchief are to be tied, while the third angle is brought forward and upwards before the scrotum." (*Op. cit.*, p. 26.)

With respect to local applications, cold ones frequently answer best, when the pain is not very severe; but, in other instances, sanguifuges and poultices are generally preferable.

When leeches are used, it is an excellent plan, after they drop off, to apply a plaster, into which the leech will not continue to bleed for some time very freely, without any occasion for the surgeon or patient to take further trouble to promote the hemorrhage. Warm emollient applications are supposed to act beneficially by their relaxing effect on the textures covering the swollen testicle.

In addition to the foregoing means, the bowels should be kept open with antimonial saline purgatives; and, during the prevalence of severe pain, or great nervous irritation, eight or ten grains of the compound powder of ipecacuanha, or half a grain of the tincture to acetate of morphia, should be given every evening.

The liquor plumbi subacetatis diffusi, with or without a small quantity of spirit of wine added to it; or the liquor ammon. acet., if no leech-bites are present; or a solution of one drachm of the mixture of ammonia in a pint of water, are all of them applications in common use, when cold cases are judged advantageous. Unless the inflammation yield quickly, the local bleeding must be repeated, and even in some cases resection. Early and increasing doses of tartaric emulsion are exceedingly resorted to. Mr. Hunter states, that he has known a scrotum remove the swelling almost instantaneously. "The effects of the vomit most probably arise from the sympathy between the stomach and the testicle." (*On the Venereal Disease*, p. 91.) Sir Astley Cooper notices certain irritable constitutions, in which the continuation of depletion will not succeed; here, says he, "the last practice, when the pulse is jerking, the patient irritable, and the part painful, is to give the subcutaneous of mercury with pulvis ipecacuanha comp."

If suppuration occur, incisions and punctures are to be applied; and, as soon as the matter can be perceived, it should be discharged, so otherwise the scrotal substance of the testicle is destroyed, and several openings, instead of one, are produced. (*Sir Astley Cooper, Op. cit.*, p. 91.)

It is generally a long time before the swelling of the testicle entirely subsides; previously to its becoming less, it usually becomes softer. "It is said much longer, (as Mr. Hunter observes,) sometimes even years, before the epididymis returns to its natural state; sometimes it is never reduced to its natural size and softness; however, this is not of much consequence, as so great inconvenience results from the continuance of the hardness simply, though sometimes, perhaps, such testicles are rendered totally useless. I never had an opportunity of examining the testicle of one that was known to have this complaint; but have examined testicles where the epididymis was but the same external feel, and where the gland of the vas deferens has been obliterated. But this I suspect seldom happens; for there are people who have both testicles swollen, and, notwithstanding, discharge their semen as before. It is in this stage of the complaint, that residents may be of service, such as mercurial friction joined with saunders." (*Hunter on the Ven. Disease*, p. 92.) Ointments, containing the hydrate of potash, are also now sometimes employed with the view of dissolving the induration; as likewise are poultices composed of vinegar and oilseed; the emulsion codon. cum hyalargene; or a lotion, consisting of granule of ammonia and rose

gar, mixed with bread. A suspensory bandage, lined with oilskin, is recommended by Sir Astley Cooper as an excellent application. Recommendations with local-mercury constitutional treatment, as small doses of the bicarbonate of mercury, or pul. hydrarg. gr. ij, acet. tart. gr. i, or extract elæagnth. comp. gr. ij, with ipecacuan. gr. ij, made into a pill, and taken every night. It must be stated, this is deemed advantageous. He speaks also generally of the effects of the liquor potassæ, the pul. hydrarg. chloridi comp., and the tincture of iodine, its effects being carefully watched.

In cystic or parietal, there is occasionally a transfer of the inflammation to the testicle; a case requiring the exhibition of liq. ammon. acet., with sulphate of magnesia, or the saline mixture with tartarized antimony, and a pill, containing opium and antimonial powder. Leeches, with a poultice, or cold lotion, are also proper. (*Sir Astley Cooper, Op. cit.*, p. 93.)

The granular swelling of the testicle, as it is termed, is a protrusion of granulations from an abscess either of the epididymis or testis, and may be the result of acute or chronic inflammation. The granulations, as they arise, being compressed by the surrounding nature of the tunica albuginea, protrude through the ulcerated opening in it, and form a swelling, which often projects through the scrotum. This disease has received the names of *fungus* and *fungus testis*, but very improperly, as it consists neither of a fleshy substance, nor of a real fungus. Sir Benjamin Rindley gives the following account of it, as an occasional consequence of chronic inflammation of the testicle: "The testicle becomes adherent to the skin at one part, and here the skin inflames and ulcerates; and then a fungus, of small size at first, protrudes through the ulcerated opening, but gradually becomes larger afterwards; and, on the surface of this fungus, you find some of the same kind of yellow substance which is within the testicle itself. What is called a fungus, however, is not a fungus in reality, but the granular structure of the testis itself." The same experienced surgeon joins Sir Astley Cooper in comparing its formation to that of *hemorrhoides*, following absorption of the lymphatics. "If (says the former) you dissect the parts in this stage of the disease, you will find, not only that the skin has ulcerated, but that the tunica vaginalis and the tunica albuginea have ulcerated also; and that the granular structure of the testicle projects through all these openings. You may ascertain the same thing in the living person; for, when the fungus is large, no portion of the testicle remains within the scrotum, and you may distinctly trace the spermatic cord into the cavity of the fungus. There are a few cases in which an abscess forms in the substance of the testicle, and bursts externally, without the protrusion of a fungus; but these are comparatively rare. The long surface of such an abscess secretes the yellow substance which I have described; and you will find large masses of it, with a laminated structure, coming out of the cavity of the abscess. The disease, if it be arrested in the early stage, leaves the testicle with the granular structure but at all impaired. If it be allowed after it has advanced some way, the granular structure is partially destroyed; but if it be allowed to run its course, the whole of the granular structure disappears; and you find in lieu of it a new formed white organized

substance, leaving the consistence of Firmament, but without its fibrous character." In the early stages, the testicle is enlarged to many times its natural size; but, when the disease is suffered to proceed, the large testicle disappears, and merely a knob or tubercle is left, connected with the slender remains of the spermatic cord. (See Benjamin Brodie, in *Ann. Med. Gaz.*, vol. xiii. p. 321.)

This disease was briefly noticed by me in an early edition of another publication, and described as "a peculiar affection of the testicle, in which a fungus grows from the glandular substance of this body, and, in some instances, from the surface of the tunica albuginea. The excrescence is usually preceded by an enlargement of the testicle, in consequence of a haemorrhage, or some species of external violence. A small abscess takes place, and bursts, and from the ulcerated opening the fungus gradually protrudes." I then proceeded to represent how unnecessary and improper it was to extirpate the testicle, on account of this affection, and recommended the fungus to be cut off, or else destroyed with caustic. I founded my advice on a successful attempt of the first kind, which was made in St. Bartholomew's Hospital, by Sir James Esdaile, a little while before my book was published. (See *First Lines of the Practice of Surgery*, p. 389.)

An interesting paper was written on the subject by my friend Mr. Lawrence, who favoured the public with a more particular account, and nine cases illustrative of the causes, symptoms, and progress of the disorder. The patient generally complains some time, or other, of pain, as the cause of the complaint; in other instances, it originates in consequence of laceration of the tunica albuginea, and sometimes appears spontaneously. A painful swelling of the gland, particularly characterized by its hardness, is the first appearance of the disease. After a certain length of time, the scrotum, resting gradually thinner, ulcerates; but the opening which is thus formed, instead of discharging matter, gives issue to a firm, and generally insensible fungus. The surrounding integuments and cellular substance are thickened and indurated by the complaint, so that there appears to be altogether a considerable mass of disease. The pain at times, and the swelling subsides considerably, when the scrotum has given way. In this state, the disorder appears very mild; but if the fungus be destroyed by any means, the integuments run together, and a cicatrix ensues, which is inseparably connected with the testicle. Mr. Lawrence observes, that if the part be examined while the fungus still remains, the excrescence is found to have its origin in the glandular substance of the testicle itself; that the coats of the part are destroyed to a certain extent; and that a protrusion of the tubuli seminiferi takes place through the aperture thus formed. Mr. Lawrence has ascertained the continuity of the connective with the pulpy substance of the testicle, of which more or less remains, according to the difference in the period of the disorder. He thinks that the glandular part of the testicle experiences inflammation; and that in the first instance, in consequence of the violence inflicted on it, and that the enlargement of the swollen substance, by the dense and myeloid-like matter, sufficiently evinces the peculiar kind of the tumor, and the pain which is always attend-

ant on this stage of the disorder. The absorption of the coats of the testis, and of the scrotum, obviates the tension of the parts, and thereby restores ease to the patient, at the same time that the fungus makes its appearance externally.

The excrescence may be removed with a knife, or, if the nature of its attachment permits, with a ligature, so it may be destroyed with sedulous applications. Mr. Lawrence gives the preference to removing the tumor in a testis with the scrotum, by means of the knife, as the most expeditious and effectual mode of treatment. He can discern no general whatever in progressing castration in this complaint, since, in no part of its progress, nor in any of its possible consequences and effects, can it expose the patient to the slightest risk. I remember the time, however, when the testicle was often removed on account of this disease. But no surgeon of the present day would ever think of such a proceeding.

Mr. Lawrence also mentions the possibility of there being other kinds of fungi, which grow from the testicle, and quotes an instance, in which Dr. Macartney found a fungus, of a firm and dense structure, growing from the tunica albuginea, while all the substance of the testicle itself was sound. Dr. Macartney was so kind as to show me the preparation, affording a clear specimen of the second kind of fungus. (See *Edin. Med. and Surg. Journal* for July, 1836.) Gallies represents the excrescence as sometimes originating from the surface of the tunica vaginalis.

Sir Benjamin Brodie, instead of cutting away the protruding mass, which he deems unavoidable, on account of the small waste being thus sliced away, keeps the tumor in the scrotum, and in this way gives him recovery; and after the protruding substance every day with daily irrigated with a weak solution of mercury, and applies over this simple dressing. Under such treatment, the surface was however covered with red healthy granulations. This he, dipped in a weak solution of copper in tannin solution, may be used as a dressing.

The reader will discern some difference in the accounts given of this disease by different writers, some representing the substance as consisting of fungus granulations; and others as being actually a protrusion of the glandular substance of the testicle itself. I shall say, that both forms of disease occur, but that they should not be confounded together.

Epididymitis, or Enlargement of the Testicle.—Sir Anstey Cooper alludes to the frequency of this disease, and to its being sometimes mistaken for one of a malignant nature. "It begins (says he) with a hardness and swelling of the epididymis, is at first unattended with pain, and is discovered by accident after it has acquired a considerable bulk." The testicle at length becomes involved, the firm of the epididymis is preserved, although its size is increased; and its separation from the testis may still be distinctly traced. The latter, when enlarged and hardened, generally retains its usual smoothness, but its form is rounder than usual; frequently, a clear transparent serum fluid is effused in the tunica vaginalis, making use of the terms in which the term *hydrocoele* is applied. "Each epididymis and testis is frequently contemporaneously affected; and hydrocoele takes exists, on one side, but not on the

other; yet sometimes on both sides. One testis may cease to swell, and the other fluid becomes enlarged. The testicle and epididymis continue to grow under great increase, and the spermatic cord is not usually increased, but its veins are a little swollen, and it is consequently somewhat increased in size. When the enlargement in the testis and epididymis is considerable, slight pain and a sense of weight are complained of in the groin and thigh. The disease may remain in this state for months, regularly increasing in size; but from disuse, a distension in riding, such as sometimes is breaking, or other cause, the swelling is disposed to increase, attended with great pain in the part affected, and swelling and redness of the scrotum. These Jacob venereux are relieved by leeches and purgatives; but, in a few weeks, as the patient again takes exercise, and returning in his usual mode of living, the disease is seen more probably to augment. The repetition of such attacks at length makes the patient anxious to have the part removed. In the course of time an abscess forms, denoted by an obscure fluctuation; and, if punctured, a thick pus of test quality is discharged. When the abscess is formed in the body of the testis, the incision always greatly retards the progress of the matter to the surface.

According to Cruveilhier, the body of the testis is affected only extensively; "and then (says he) either the tubercular inflammation takes place along the fibres radiating from the corpus, which, proceeding from the corpus testicularium, penetrate the substance of the testicle; or else tubercles, more or less numerous, form at different points of the texture of that organ." (*Cruveilhier, Anat. Pathol.*, *liv.* 2.)

Sir Benjamin Brodie represents the testicle as being at first somewhat knobby and irregular; but, as it increases in size, and becomes harder, the different knobs seem to run into one another, and, at last, the part constitutes one huge, hard, uniform oval swelling. He admits that the disease generally commences in the epididymis, but not always. (*See Lond. Med. Gaz.*, vol. xlii. p. 220.)

In the dissection of a testicle thus affected, a yellow increased matter is found collected in small masses in its glandular structure; and, in a more advanced stage of the disease, these masses are larger in certain places; while, in others, the glandular structure retains its natural appearance. All this is well represented in Cruveilhier's 9th *Lithiogr.* pl. 3. In a still more advanced stage, the yellow deposit forms distinct hard masses, and generally runs in two knotted. (*See B. Brodie.*) Dupuytren also describes the tubercular degeneration as one of the principal characters of the disease; and he states that, in most instances, it affects the intercellular tissue around the epididymis, and also the substance of the testicle itself. (*Clin. Chir.*, l. i. p. 101.) Cruveilhier, who has published an accurate description of it, illustrated by plates, regards it as the result of chronic inflammation of the epididymis. (*Anat. Pathol.*, *liv.* 1. pl. 1.) In what Sir Ashley Cooper terms the adhesive stage, the testis and epididymis, when dissected, have a general yellowish appearance, and considerable softness. "When (says he) I make a section of a chronic enlargement of the testis, throw it into water, and agitate it, a whitish yellow fluid proceeds from the seminiferous tubules, which are extremely dilated, and the liquor coagulated. But still the same bulk of the

testicle remains, owing to the cellular membrane of the part being loaded with a yellow fibrine; the rete is filled with the same secretion as the tubule: the epididymis is similarly diseased; and sometimes the testicular scirrhus and vasa deferentia are distended with a similar deposit. Cruveilhier gives an example, in which all these parts, and also the spermatic ducts, and prostate gland, contained tubercular matter. Sometimes abscess and phlegmonous matter, and in this case a part of the testicle is destroyed, and the complete recovery of its functions is impossible. Occasionally disease lead into those diseases, the cellular and arteries of which, still accepting semen, are prevented from closing till the secreting surface be healed or destroyed. (*Sir A. Cooper, Op. cit.* p. 37.) The protrusion of high granulations from such abscesses, and termed the granular testis, I have already noticed. Chronic inflammation of the testicle sometimes comes on as a consequence of local injury; but much more frequently as the result of some constitutional derangement, as that from syphilitic rheumatism. (*See Dupuytren, Clin. Chir.*, l. i. p. 88; *Sir B. Brodie, &c.*) According to Sir Ashley Cooper, a often takes place in persons who have been scrofulous in their youth. (*Alb. Dupuytren, vol. cit.* p. 308.) It is frequently the product of a constitutional worm and leads to be interperence. It also follows a long course of mercury; and "it arises in habits in which the vital powers are diminished, and in which we often find a loosening of the cellular membrane in the form of chronic catarrhs. Frequent exposure to wet, cold, or fatigue, and an excessive indulgence of the passions, also dispose to its production. The most frequent accidental cause of syphilitic disease?" (*Sir Ashley Cooper, Op. cit.* p. 30.)

Most of our constitutional secretaries are represented by Cruveilhier as generally beginning in the body of the testicle, tubercular secretions in the epididymis. "The former (says he) are commonly spermatic; the latter mostly arise either from a venereal cause, a scrofulous constitution, or a carcinoma." (*Anat. Pathol.*, *liv.* 1.)

When chronic enlargement of the testicle arises from syphilis, it is sometimes called the *elephant testis*. The eruption of this case, so far as the part itself is concerned, has not hitherto been well ascertained. Indeed, Sir Benjamin Brodie observes, that under whatever circumstances chronic enlargement of the testicle takes place, "the symptoms are precisely the same." He has not overlooked, however, its combination with venereal ulcers, or eruptions, as throwing light on the cases. (*Nat. cit.* p. 227.) Dupuytren remarks, that "it would not seem difficult at first to distinguish venereal enlargements, as those produced by syphilis, from others which are scrofulous: I must confess, however, that, in many examples, they begin absolutely in a similar manner, and do not exhibit their true character till after a certain space of time has elapsed. The scrofulous (he says) do not generally yield to ordinary means; they are indefinitely protracted, are often accompanied by affections of the same nature, and are collected with a scrofulous continuation." (*Clin. Chir.*, l. i. p. 300.) The atrophied chronic enlargement of the testicle is mostly described as coming on without pain or tenderness, except that produced by more distension and the weight of the disease; but, according to Mr. Cusack, the inflammation some-

sionally recurs or rather suddenly, and in a sub-acute form. The disease "commences in the body of the testis; there is little alteration in the form of the organ in the first instance; but, as the enlargement advances, the tumour becomes more globular, the epididymis soon becoming involved, and loss in the scrotal mass; the tumour has a fleshy feel, but differs much in density in different parts. It is said to be somewhat uniform on the surface, and generally a certainty is so generally partial adhesion in the cavity of the tunica vaginalis, however, confined with effusions here that cavity, even independent of the internal changes which they are going on, render this a very uncertain symptom; so uncertain, indeed, and so little uniform are the primary appearances that Mr. Casak believes the best practical figures would be unable to make a perfect diagnosis, if unacquainted with the history of the case and the attending circumstances. The termination of the disease is either resolution, or suppuration, or infarction, and the formation of granular follicles, ending in total destruction of the function of the organ. Mr. Casak has stages to follow, and is able to affirm, from his own experience, that this affection of the testis is met with in the earlier stages of secondary symptoms, or during the presence of any of the forms of true popliteal claps." (See *Edin. Journal of Med. Science*, vol. viii, p. 531.)

"The acute form attended in most with accompanying venereal lentic pains in the testes, and either a scaly scrofula, or perhaps a solitary spot, apparently belonging rather to the genus Acne; but these are instances comparatively rare. The patients who suffer from this form of the disease, amount to labour under affections of the peritonitis and leucæ, and bear the marks of having suffered from pustule and tubercular eruptions." (See *Edin. Journal of Med. Science*, vol. viii, p. 531.)

I once attended with Mr. Donoghue, of University College, a terrible example of phlegmonous abscess of the penis, followed by painful enlargement and ulceration and abscess of the testis, one of which presented the form of a large fungus-like mass, and gradually sloughed away. The patient ultimately fell a victim to the further ravages of the disease. With respect to the diagnosis of a venereal chronic enlargement of the testicle, Dupuytren observes that we daily meet with patients who have a swelling of this organ, for which they are obliged to cauter. They have not received any blow or external injury; the swelling has subsided and attacked the other testicle, or has continued in one or the other as the person lives. "If the tumour is old, or cystic, comes on insidiously, and is attended with a thickened pain when touched, the patient has had old venereal complications, and one testicle, after having been diseased for six months, a year, or a year and a half, has resumed its healthy state, and been followed by disease of the other; there is strong reason to presume that the case is of a syphilitic nature, for a cancerous affection would not thus change its place." (See *Dupuytren*, in *Ch. Clin.*, t. i, p. 167.)

In chronic enlargement of the testicle, though a mild syphilitic may have taken place in the testis, and even in its substance, or epididymis, a cure is yet practicable. This opinion, deduced by Sir Astley Cooper from a full of intimate experience, and delivered by him in his lectures, receives confirmation from every quarter. "A person (says Mr. Cruveilhier) que dans l'état de l'écoulement, les inflammations du testicule

becomment, dans l'épididyme et même dans le corps du testicule, ne sont pas des raisons suffisantes pour l'expectation." (Anat. Pathol., liv. ix.) Sir Astley Cooper directs the patient to observe the recommended position for a month, as he to prevent excitation of the blood into the affected organ. Three grains of calomel and one of opium are to be given every night and morning, and the parts kept bare for at least a month. Every fourth morning a decoction draught with half an ounce of sulphate of magnesia, and fifteen or twenty drops of tinct. iod. is to be prescribed. Leeches are to be applied twice a week, the scrotum dressed three a day, and a lotion of the liq. ammonia. acet., with spirit of wine sulphuric, or else equal parts of castor oil mixture and vinegar. (See *Sir Astley Cooper*, Op. cit., p. 40.)

If mercury be employed, when the disease has not been going on more than two or three months, the testicle will generally be restored to a healthy state; but at a later period, it will not accomplish so much. The mercury will only soothe inflammation that exists, without having the power to remove the structure which has been already destroyed. Mercury may now relieve the pain and tenderness, and diminish the swelling; but some induration and enlargement will remain, over which mercury has no control. (See *R. Brede*, in *Ann. Med. Gaz.*, vol. xii, p. 222.) If calomel or the blue pill disagree with the stomach, mercurial ointment should be rubbed on the thigh. When the swelling is combined with a syphilitic eruption or ulcers, the bichloride of mercury joined with sarcaparilla will sometimes prove the best medicine. Dupuytren found, that small doses of the bichloride had a better effect than full ones; his custom, therefore, was to give three a day one pill, containing $\frac{1}{2}$ of a grain of the bichloride, $\frac{1}{2}$ a grain of extract of opium, and 2 grains of extract of guaiacum. The dose was very gradually increased to $\frac{1}{2}$ a grain of the bichloride, which quantity was never exceeded. The compound decoction of sarcaparilla and codonides were likewise prescribed. (See *Ch. Clin.*, t. i, p. 89.)

When chronic enlargement of the testicle is in the form of hydro-sarcosis, the fluid in the tunica vaginalis is usually absorbed under the influence of mercury, and the same remedies which cure the disease of the testicle, cure also the hydrocele. "There are cases, however, in which the hydrocele attains a large size, and in which the remedies which cure the testicle are not equal to the cure of this secondary disease. Under these circumstances, you should treat the disease of the testicle first by the exhibition of mercury; and after a mercurial course, but not till then, you may inject the hydrocele." "What would happen (asks Sir Benjamin Brodie) if you were to make an error in the diagnosis, if you were to mistake a hydrocele of this kind for a cancerous hydrocele, and inject it before you had cured the primary disease? I did (says he) in one instance—make this mistake, and I will tell you the result. A gentleman (a West Indian) many years ago consulted me about a hydrocele. There was a considerable collection of fluid, perhaps about eight ounces; I found the scrotum somewhat indurated, which I thought was merely from thickening of the tunica vaginalis; I did not, therefore, hesitate to inject the hydrocele. After the operation, no violent inflammation followed, but it did not subside as usual,

small abscess formed in one part of the testicle, which I opened. After this, several abscesses formed in succession in the testicle, which, all the while, went on growing larger and larger. Now I began to see the error which I had committed, and to suspect that the patient laboured under a chronic inflammation of the testicle, the hydrocele being merely a secondary affection. I put the patient under the influence of mercury, and of iodine, so that it acted on the glands, the abscesses ceased to form, the testicle rapidly became reduced, and, in short, another mistake, there was an end both of the disease in the testicle and of the hydrocele; so that, in fact, every thing turned out as well as if I had adopted the proper mode of treatment in the first instance." (Sir B. Brodie, *Op. &c.*, vol. xiv. p. 225.)

Singularities of the Testicle.—I have already noticed the opinion of Baillie, Jussaye, &c., that, although it may not seem difficult at once to distinguish an enlargement of the testicle produced by syphilis, or by an external injury, from another which is scrofulous, yet, in their beginning, they sometimes absolutely resemble one another, and their true character cannot be made out till a later period. "In general (says he) scrofulous enlargements do not yield to common treatment; they continue indolently, are frequently accompanied by other affections of the same nature, and are collected with a stercoraceous consistency." (See *Chir. Clin.*, t. i. p. 101.)

The following is the description given of the scrofulous testicle by Sir Benjamin Brodie. The patient experiences a slight pain in one part of the testicle, and there a little enlargement is felt, generally at one end of the epididymis. Then a slight pain is experienced at another part, and here is perceived another enlargement, which is commonly also in the epididymis. These small tumours increase in size, and gradually become more painful. Sometimes as many as three or four of these tumours are found on the surface of the testicle, generally connected with the epididymis. The skin becomes adherent to them, and one of them is converted into an abscess, which bursts through the external skin. A similar abscess forms in another, and runs the same course. These abscesses discharge very little matter, and they do not heal but a healthy abscess. When a probe is introduced into one of the sinuses thus formed, it passes down into the centre of the testicle, or thence in which the abscess originated. In some instances, the disease will go on, until the whole of the testicle is disorganised. Sometimes it is confined to one testicle; sometimes both are similarly involved. Occasionally it will completely destroy one of the testicles; but, more frequently, the testicle is only partially affected, and a great deal of the scrofulous structure remains in a natural state. In the advanced stage, the testicle sometimes becomes enormously enlarged, and hard throughout, except on external examination, the remains of the prostatic urethra, which extend to the beginning, may be perceived. The disease is generally connected with other scrofulous symptoms; an enlarged gland in the neck, scrofulous disease of the spine &c. &c. or of some of the joints. (See *Lenten Med. Gaz.*, vol. xiii. p. 377.)

It is remarked by Jussaye, that the tubercular degeneration is one of the principal char-

acters of these scrofulous enlargements. In the majority of cases, he says, the disease attacks the fibres of the testicle, surrounded by the epididymis, but that it may also occur in the substance of the testicle itself. The tubercles are developed slowly, and may contain three or four grains. The mode in which they increase, their progress, their long duration, or the signs indicative of their nature. "Scrofulous swellings of the testicle are not confined to a certain age; but they are hardly then those which depend upon inflammation. They are free from heat and redness; and cause a loss of weight and vigour. The scrofulous cellular tissue is uniformly free," he further, Dupuytren should have said it is so, except at the points where abscesses adhere to the surface. "The shape of the tumour is commonly irregular and irregular, while, in a scrofulous enlargement, the testicle is globular, and the epididymis knobby; the systematic cord being nearly spared, but torn and then implicated. As the scrofulous disease of the testicle makes progress, various points within the organ soften, and, when touched, seem as if they contained a soft substance. Soon after the small whitish projections are noticed, the skin thickens, and from the openings is discharged a thin pus, and a yellowish cheese-like or glutinous substance, evidently a product of scrofula. Pustules are next formed, out of which is voided a stercoraceous kind of pus. The disease may go on for years." (Jussaye in *Chir. Clin.*, t. i. p. 301.)

The testicle, even in very young children, sometimes becomes enlarged and very hard, but without pain; and this indolent increase of it may remain for many weeks, months, or years; and, as the health improves, ultimately subside. More frequently the disease comes on at puberty, or between that period and the age of twenty; and, not uncommonly, it attacks both testicles. It suppurates early, which happens even in children, but still more frequently at puberty, the matter often forms in the glands major of the epididymis, though sometimes in the glands minor. According to Sir Astley Cooper, the body of the testicle rarely suppurates "but, after the epididymis has ulcerated, the testis becomes affected, and the scrotum assumes a firm line; ulceration comes, and an abscess forms, which discharges ill-formed pus, and some sperm, at least until the age of puberty; and the opening is extremely difficult to heal, continuing six months, and even for years." The whole testicle is at length wasted, and but a small portion is left, and the seminal secretion almost entirely ceases.

In dissections of the epididymis and testis affected with scrofulous disease, Sir Astley Cooper has found a yellow spot surrounded with a zone of inflammation in the glands major, or sometimes, though less frequently, in the glands minor. When the spot ulcerates in its centre, the matter which is voided is not pure pus, but composed of fibrine and serum, and having a slight yellow tinge. "In the testis there are several solid or yellow spots, accompanied by the same kind of inflammatory case; and several yellow streaks are also found within the testis. Scrofulous abscesses in the testes are sometimes accompanied by a granular swelling like that which exists in the simple chronic disease." (Sir Astley Cooper, *Op. &c.*, p. 92—93.)

Mercury, which proves so efficient in the ordinary chronic enlargement of the testicle, does harm in the serous disease of it. No specific remedy for ascitis is known; but the patient should have the benefit of pure air, and especially of that of the coast. The diet should be antiscorbutic, and ale, or porter, or wine and water to be drunk at dinner. Sir Astley Cooper speaks also in favor of tepid sea-bathing. The medicines which he recommends, are hydr. cum creta with rhubarb; powder of columba with opium and soda twice a day; vitrum argy. three times a day; liqor. ferri ammon. or pills composed of rhubarb and carbonate of iron; quina with infus. rose comp.; liqor. potassæ; the tincture of mercury in dilute doses, joined with the compound decoction of sage and flax, or with tincture of bark, or of rhubarb.

Sir Benjamin Brodie remarks a regulated diet, residence at the sea-side, and the exhibition of steel medicines, or quinine, where they seem to be required, as they generally are. But he has seen more benefit derived from the liquor potassæ than any other medicine. It is to be continued with tincture of quinia, and taken in the dose of half a drachm three times a day, blended with a wineglass of table-wine. The acetate of potash, which may be produced by this mixture, Sir Benjamin conceives has also a good effect by acting as a diuretic. (*Edin. Med. Jour.*, vol. xiii. p. 378.) Preparations of iodine are well known to be serviceable in this disease; and the tincture, or what is better, the iodured solution of the hydrate of potash, may be exhibited with caution.

In the indolent stage, previously to suppuration, the osmament of iodine, or iodineum hydrargyri, may be rubbed on the part, the caloplastum hydrargyri applied, or lotions of the liquor ammon. acet. and opii, sin. used. If the disease suppurates and ulcerates, a solution of one grain of sulphate of copper in an ounce of distilled water may be employed as a lotion, and also as an injection for the sinus, or for cauterizing and hyalizing the sinus; 30 minims of silver lotion are also eligible.

The cystic, or, as Sir Astley Cooper names it, the *hydatid*, or *encysted disease of the testicle*, is comparatively rare, and described by him as a specific, yet entirely a local disease, as he has seen it in persons who enjoyed excellent health, and in whom no relapse occurred after the part had been removed. It is chiefly met with in persons between the ages of 18 and 35; and is alleged to begin with enlargement of the epididymis. It is not painful until the part is large, and the swelling hinders circulation makes pressure on it. When handled, there is no feeling of tenderness manifested, unless the pressure be considerable. The frequently heaving look of the patient is apt to create suspicion of hydrocele. The spermatic veins and those of the scrotum are distended. The natural form of the testis is preserved, being rounded in front, and flattened at the sides, and not so pyriform as in hydrocele. When the swelling is heaved, it communicates an impression that it contains a fluid, for it easily yields to pressure; yet there is no true fluctuation, for the tumor does not rise at one distance, as it sinks under the pressure of the finger; but it yields only at the spot compressed. If strongly compressed, a sickening pain in the groin and loins is produced. The weight of the testicle is obviously increased, and after a time, this causes pain in the flanks; so-

tion, and its bulk is a great inconvenience. The complaint seems to Sir Astley Cooper to be so local, that were it not for its weight, and size, it would scarcely call for removal; for the spermatic cord does not become affected, nor are the adjacent glands of the loins or groin irritated by it.

In the dissection of this disease, the tunica vaginalis is found thickened, and partially adherent; and the tunica albuginea, both of the epididymis and testis, is much denser than natural. The testicle consists partly of a solid structure, and partly of cysts, varying in size from that of the head of a large pin to that of a small marble. The small cysts contain a transparent, yellow, serous fluid; the larger, a mucous secretion. The cysts which contain serum are highly vascular. Sir Astley Cooper suspects the cysts to be enlargements of the seminiferous tubes from obstruction; and on this point he is doubtful. He admits that they are certainly not of the nature of animal hydatids. The cysts in the epididymis do not become so large as in the testicle. There are some fine specimens of this disease in the various pathological museums of London; the best which have been seen are in those of the late Mr. Abernethy, and of Mr. Liston.

The marks of distinction between this cystic disease and hydrocele, are that the former is characterized rather by a yielding than a fluctuation; by a heavier swelling; by the swelling being less pyriform than a hydrocele; by the entire absence of transparency; by the sickening pain caused by strong compression of the tumour; and by the dilated state of the veins of the spermatic cord and scrotum.

The removal of the part by operation is the only means of relief; for the change of structure, attending the disease, manifestly amounts to a disorganization of the part not admitting of benefit from any internal or external remedies. "A system of depletion and abstinence for a week (observes Sir Astley Cooper) will make the patient bear the operation well; and it is one which, for this disease, I never knew unproductive." (*Op. cit.*, p. 88.) The following modification of this statement, however, deserves well to be remembered. "The largest (epididymary) and encysted disease may be contained in the same testis, and then the case may prove fatal; but this will be ascertained by the dissection of the removed part, which will lead to a favorable prognosis in the encysted disease, and to a very decidedly unfavorable opinion in the other. Cruveilhier (*liv. v. pl. 1, figs. 1 and 2*) has given a most correct view and description of one form of the latter unfortunate condition, which he terms *cancer albugineus testis matris pedis*, on account of some of the cysts containing a pearly-colored substance, but others a brown fluid, and others again a puriform matter. In this case, castration was performed, and the wound quickly healed; but six months afterwards, medullary tumours formed in the substance of the bodies of the spermatic vessels and both dorsal vertebrae, and by compressing the medulla, excruciating paralytic, first of the upper, and then of the lower extremities, ultimately paralytic, &c., terminating in death.

Medullary Cancer of the Testis. *Fungus Hæmatodes.* *Psalpy Testicis.* *Medullary Epithelioma.* *Fungoid Disease of the Testis.*—Organic diseases of the testicle are feared to be less common at the present time than they were believed

to be formed, when chronic enlargements of that organ were always confounded with them. The discrimination of one class of cases from the other, the result of which has been to render the extirpation of this part a comparatively rare operation, appears to me to be one of the greatest improvements in modern surgery. Medullary cancer of the testicle, a disease bearing such a variety of names, usually begins with an enlargement of the body of the organ, which is at first attended with considerable hardness, and the swelling often increases remarkably, "so that in three or four months, the whole of the testicle will become enlarged. It then affects the epididymis from one extremity to the other. While the complaint is confined to the testis, the swelling is globular; but when the epididymis is also diseased, it becomes pyriform, and has so much the form of hydrocele as at first sight to be easily mistaken for it. This deception is rendered the more easy, as a small quantity of water is often effused, so that the cavity has been called *hydro-sarcote*. When carefully examined by manipulation, the solid swelling is felt through the water, and the sides are found flatter than its top, which is the form of the testicle in its natural state. The surface of the testicle is frequently uneven; but this symptom is not a concomitant of this disease in its early stages. At first the complaint is not painful; but it is soon followed by occasional darting pains in the part, and in the course of the spermatic cord or the groin and loins, and, if it be much hindered, it leaves a tenderness and increased pain in the part. Its growth is very uncertain; it sometimes increases quickly, and acquires great size; at others, eight or ten months elapse, before the swelling is considerable. It also does not grow steadily and equally; but becomes very painful for two or three days, and during that time rapidly increases; and then it is stationary for two or three weeks." At first, the colour of the scrotum is not changed, and the spermatic cord is not swollen, excepting that the veins are slightly enlarged. In the second stage, it is covered with varicose veins, and the testis, instead of being hard, yields to pressure, and both the elastic feel and the pyriform shape of the tumour raise a suspicion of its being a hydrocele. The spermatic cord becomes enlarged up to the abdominal ring, and the spermatic veins are fuller than natural. The patient's countenance is sallow; sometimes he is emaciated, sometimes he has profuse diarrhoea; his appetite fails; his rest is interrupted by pain; and he falls into a state of great exhaustion.

In the third stage, the testicle becomes adherent to the sperm, and the skin can no longer be readily moved over the tumour. In the groin on the diseased side, one or more abscesses glands enlarge from irritation; and after many glands there have become affected, those in the opposite groin also enlarge. The surface of the testicle now feels knobby and unequal; and sometimes the spermatic cord, besides being enlarged, indurated, and varicose, becomes adherent to the pubes, and at this point the testicle is firmly bound. At length, at a particular point of the scrotum, a purple blush appears, under which a fluctuation seems so distinct, that the surgeon is often induced to make a puncture; but merely blood is discharged. Although the wound thus made heals, yet soon afterwards ulceration ensues, and a fungus, pyæmia, blood,

and discharges a profuse quantity of thin serous fluid, which has a peculiar salt about it. In two or three weeks, the ulcer spreads to the breadth of the palm, sloughs frequently, is extremely offensive, occasionally very painful, but not tender to the touch; and if the testicle be compressed, a brain-like substance issues from the fungus. At last, the patient sinks from want of sleep, from discharge, and continued irritation. (Sir Astley Cooper, Op. cit., p. 118-120.) I have never seen the disease in that advanced condition where ulceration has occurred, and a mass of fungoid substance has protruded. I believe, with Sir Benjamin Brodie, that the impossibility of doing so are rare, because the testicle is generally unattached, or the patient dies long before the disease gets to this point. It is certain that the tumour may grow to an enormous size, without any alteration of the scrotum, or protrusion of the medullary substance taking place. In one or two examples, in which I was led by the elastic feel of the tumour to make a puncture, the wound healed up, and never gave any further trouble. This agrees with the observations of Sir Benjamin Brodie; but I should remark, that the punctures in my cases were made at an earlier stage than that referred to by Sir Astley Cooper, the purple blush not presenting itself at the point where the lancet was introduced.

The writings of Professor Cruveilhier convey most accurate views of the chief characters of medullary cancer, or cephaloma, as he calls it. In his able work, entitled "*Essai sur le Cancer de l'Élémentaire Forme de Brame*," this subject is considered in a manner which cannot fail to be highly interesting to every surgeon into the pathology of surgery. But as I have noticed his statements in other articles, (See CANCER, and FUSCIGENOUS,) it is unnecessary here to repeat them. With respect both to testicular and medullary cancer, sometimes the new deposit takes place in the molecular structure of the part affected, after the manner of carcinoma; while, in other instances, it is thrown out on a free surface, rather as the manner of secretion; or, as Sir Benjamin Brodie has explained, there are some cases, in which a particular organ loses its natural structure, and becomes converted into a diseased one; and there are other cases, in which the morbid growth is altogether a new formation—a tumour, growing in a particular part of the body, which remains entire, and retains its natural organization. Now, with respect to medullary cancer, or *fungus haematoideus*, it appears that, in some cases, the glandular structure of the testicle is actually converted into this diseased structure; but there are others in which the new deposit reflects in a distinct mass, and the glandular structure of the testicle is, for a time at least, entire. Sometimes the new deposit accumulates in a mass in the centre of the testicle, and the glandular structure is expanded, as a thin layer, upon its outside. Mr. Wardrop relates a case, in which the glandular structure was natural, the tumour having grown from the surface of the right testis, immediately beneath the tunica albuginea. Sir Benjamin Brodie refers to a specimen, in which the glandular structure of the testicle is actually converted into this diseased mass, while there was a large medullary tumour completely occupying the cavity of the tunica vaginalis. Whenever distinct the testicle may have been in the first instance, it becomes at last converted with the disease; and there is then a tumour of an oval shape, and in this respect different from hydro-

cells. It is also harder than a hydrocele; opaque instead of being transparent; harder in some parts than others; and without the smooth regular surface of hydrocele. The volume and elasticity of the tumour, however, have often caused it to be mistaken for hydrocele, and "parietaria." (See *Monro on Purgas, Hemorrhoids, &c.*, in *Med. Chir. Trans.*, vol. iii. p. 63.)

Notwithstanding the decided feel of fluctuation, dependent on the elasticity of the swelling, a well-informed surgeon will accurately arrive at a correct diagnosis; but if there be doubt, Sir Benjamin Brodie sometimes punctured the tumour with a very small incision. "If it be a hydrocele, the serum escapes, and the tumour disappears; but if it be parietaria, there comes out a little blood, and that is all. No harm is done by the puncture." The identical test escapes, and the wound heals. (See *B. Brodie, in Trans. Med. Soc.*, vol. xii. p. 303.)

I have already mentioned the occasional combination of the disease with hydrocele, constituting one of the cases, sometimes termed *hydro-sarcocoele*. More frequently, the cavity of the tunica vaginalis is obliterated by adhesion; or there may be partial adhesions, and partial hydrocele.

In the dissection of a testicle, which was the seat of this disease in the early or first stage, Sir Astley Cooper found, that the excessive tumescence of the part did not arise from the solid nature of the substance deposited in it, but from the excessive distention of the tunica albuginea, and from its increased yielding to the pressure from within. "The substance which was external was globose, of a yellowish white colour tinged with blood, partially vascular, and, when incised, it became flocculent, and had the appearance of matted wool. The seminiferous tubes could be observed at that part of the testis; but, in other parts, they remained entire. In the dissection of the testis in the second stage of the disease, it is found filled with a similar soft and white fibrous matter, which occupies the testis and epididymis, and the parts of which readily yield to pressure. And there is intermixed with the soft condensation a yellow fibrine." When incised in this state, the soft fibrine is retracted, and the testicular septa of the testis in which it has been exposed are left, representing a kind of cellular straggles. In the third stage, when the testis is excessively enlarged, the tunica vaginalis contains a good deal of fluid; the tunica albuginea has given way, and a portion of the diseased projects through it. The interior of the testis may likewise contain cysts of serum, as well as coagulated blood, and the white soft fibrous matter closely reflected, from which, when compressed, a substance issues like cream tinged with blood, and sometimes coagulated to pinted lumps; the epididymis is enlarged, and when serum has not been effused, the vascular signals are adhering to the testicle. (See *Astley Cooper, Op. cit.*, p. 121.) The same distinguished surgeon notices the frequent enlargement and induration of the spermatic cord, and his explanation from the disease in certain other cases which have even had a fatal termination. On this point Sir Benjamin Brodie remarks, that "when the disease first exists, the spermatic cord is in a natural state, and, in many cases, it never seems to be much enlarged; but, in other instances, the disease extends to the spermatic cord, and this to a very great extent.

Seeing this, you will not wonder that disease should take place in the testis, when some parts of the spermatic cord originate. The disease, however, will show itself in the testis, although the spermatic cord be healthy. This I have seen many times in examining bodies after death." (See *Lect. Med. Gen.*, vol. iii. p. 408.) The same fact was exemplified in a case in University College Hospital, where, at the autopsy on the body of the patient, a man about 30, I observed a testicle affected with this disease; and, though the afterwards felt a tumor in an extensive measure of the same nature in one of the lumbar glands, the portion of the spermatic cord removed, and also that left within the inguinal canal, were free from disease. In another case where I operated, the part of the cord taken away contained little bodies like millet seeds in size; and, notwithstanding this extraordinary circumstance, the patient recovered, and was apparently in health, at least two or three years after the operation; and, so far as I know, my own patient well to the present day, which is six or seven years from the time when the testicle was removed.

Frequently a quantity of serum is found in the abdomen, and behind the diaphragm, "a large tumour, to which that immense adhesion on the forepart, and the aorta and vena cava are placed behind it. It is in different subjects of a size from that of the clenched hand to that of the head of a child. When cut into, it contains a soft, but still a solid fibrine, with which is intermixed a fluid like cream, slightly tinged with blood. In some persons, the tumour in the abdomen begins from the lower part of the liver, and extends to the diaphragm, involving the kidneys; and, when it is attempted to be dissected, a large quantity of a thick cream-like matter bursts from it at different parts. The aorta and vena cava are dissected, and numerous tubercles and effusions are produced in their coats, and fungus (mucillary) effusions into the cavity of the aorta." In many of these cases the mesenteric glands are similarly diseased. Frequently the liver is loaded with tubercles of the same nature; and in the museum at St. Thomas's Hospital is a preparation in which the thoracic duct is obliterated by this disease. (See *Sir Astley Cooper, Op. cit.*, p. 121-124.) In an example dissected by Mr. Lawrence, the swelling of the testicle consisted of cellular septa, filled with pulpy matter; numerous tubercles of the disease were found in the osmentum, and in various parts of the pelvis, intermixed with recently effused coagula. A mass of soft matter, equal in size to a man's head, lay on the spine, behind the aorta and vena cava, which last vessel was closed for some extent. The spermatic vessels could not be found. (See *Med. Chir. Trans.*, vol. vii. art. 18.)

The young man from whom I procured a testicle in University College Hospital, an example of this disease, was afterwards destroyed by the effects of an enormous swelling of one of the lumbar glands, which was as large as a man's head. It not only compressed the diaphragm and vena cava, but a portion of it had made its way into the pelvis of the kidney. This patient suffered excessive pain for several weeks before he died, and was reduced to an extreme state of emaciation, the stomach having been able to retain scarcely anything in it. The swelling of the lumbar gland could be plainly felt through the abdominal parietes. It is covered by the

B. Brodie, that "in many cases the tumour in the loins gives the patient no pain, and but little inconvenience; while, at other times, it is attended with the most extraordinary suffering. A gentleman (he adds) with whom I was acquainted many years ago, had this disease of the testicle; Mr. Cline was consulted, and he recommended the amputation of the testicle, and performed the operation. A year afterwards, the patient became weak in his lower limbs, and at last they became completely paralytic. He died; and, on examining the body after death, there was found a large tumour in the loins, which had affected the vertebrae, so as to put pressure on the medulla spinalis; thus accounting for the paraplegia." (*Sir B. Brodie, in Lond. Med. Gaz.*, vol. xiii, p. 406.)

Dr. Macdonald has recorded 26 instances, in which the patient died of peritonitis; the particulars contain several circumstances in the preceding account. "The abdominal cavity contained a great deal of sero-purulent fluid. The peritoneal coat of the stomach and intestines was extensively inflamed; and covered with patches of lymph. The liver was enlarged, softened, and had a mottled appearance. There was a tumour nearly as large as a child's head, situated under the transverse arch of the colon, and covered by the small intestines. *Refray* clung upon the spine, and was firmly attached to the duodenum, liver, and left kidney. A section of the mass showed it to be composed of a soft brownish substance, which resembled brain mixed with blood, and from the more solid parts a fluid, like yolk, was squeezed out. The inferior part of the testicle presented the same appearance and structure as the abdominal tumour, but the upper half was firm, grayish, and slightly fibrous. The epididymis was enlarged; the tunica albuginea thickened. &c. The spermatic cord was sound." (*See Macdonald's Hospital Reports.*)

In Sir Astley Cooper's valuable work on the *Structure and Diseases of the Testis*, is an interesting plate (viii.) representing the appearance presented in an instance where the castration had been performed, but a relapse occurred. There the end of the spermatic cord is seen forming a considerable tumour; a large tumour may be noticed in the groin; and a very considerable mass between the left kidney, ureter, and sigmoid flexure of the colon.

The only chance of a cure (and this is a very poor one) must be derived from the early performance of castration, before the disease has extended to the tubular or testicular glands, or far up the spermatic cord. Indeed, every little hope should be placed in the removal of the testicle; for cancer humours appear to be either constitutional, than a local disease. Nearly every case on record has terminated fatally, and, upon dissection, either the liver, the lungs, the brain, the limbs or musclicular fibres, or other internal parts, have been found affected with the same disease. In one case dissected by Mr. Lawrence, tubercles of a similar structure to the disease in the testis, were found in the lungs, heart, and, as shewn, in nearly all the other organs and abdominal viscera, though the contents of the scull were free from disease. (*See Cases related by Warton, Earle, Langstaff, and Langstaff, in Med. Lib. Tenax*, vol. iii. and viii.)

Mr. Travers states, that he has never known an instance of the relapse of the disease after castration. (*See Med. Lib. Tenax*,

vol. xvij, p. 339.) And see Astley Cooper observes, that of all the operations of surgery, there is scarcely any which is so generally successful as that of castration for this disease; and there is no hope of the patient's life being saved, unless the operation be performed as soon as the nature of the complaint is ascertained. (*Ips. cit.*, p. 331.)

Dr. Baillie observes, that the testicle is often found converted into a hard mass of a brownish colour, and generally interspersed with humours. Sometimes there are cells in the tumour, which are filled with a creamy fluid. (*Medical Anatomy*, &c., pp. 352, 353, ed. 2.) This is what is usually termed the *scirrhous testicle*, which is attended with great hardness, severe pain, depending along the spermatic cord to the loins, and in unequal knotty feel. In general, the health becomes impaired. To use Mr. Pott's words, sometimes the fury of the disease breaks to rest, but making its way through all the membranes which envelope the testicle, it either produces a large foul, thickening, phagdenic ulcer, with hard edges, or it bursts forth a painful clotting fungus, subject to frequent hemorrhage. (*Pott's Chir. Works*, vol. ii, p. 330, edit. 1808.)

Pott's description probably comprehends several forms of disease, and confounds them together, as for instance fungus phagdenic, scirrhous cancer, and even chronic enlargement with formation of ligamentous granulations and a portion of the substance of the testicle. Now, it deserves attention, that the kind of disease formerly recognized by surgeons as *scirrhous* had center of the inside, and specified by Dr. Baillie, is found at the present day to be an all kinds of a common occurrence. Mr. Travers declares himself "incredulous as to the fact of the scirrhous cancer affecting the testis." (*Med. Lib. Tenax*, vol. xvii, p. 327.) Sir Astley Cooper remarks—"I much doubt the existence of this disease in the same form and appearance as it assumes in the breast, viz., an excessively hard swelling, interspersed by a network of strong fibres, or bands. I have seen a few instances of a very solid enlargement of the testis, accompanied with great weight, attended with severe occasional pain, beginning at the body of the testis, never becoming soft, like fungus, or producing a fungoid and very vascular bleeding surface, and being tuberculated, irregular, and excessively hard, but never becoming so large as the fungus disease; the pain extending to the loins; the spermatic cord enlarged, hardened, and thickened; a smaller tumour than that of the fungus disease, forming in the abdomen; some water is secreted into the tunica vaginalis." At length, a description of the disease into the cellular membrane of the leg and thigh of the diseased side is prototypically, and then the other leg becomes similarly affected. On dissection, instead of the scirrhous tumour, a hard white substance is found in the bodies of little vascularity, and sometimes interspersed with small particles of cartilage, or bone. The epididymis contains the same kind of substance; and the spermatic cord, which is enlarged, has small white nodules in it. The tumour in the abdomen is also of a white solid texture, very unlike that of the fungus disease. This disease has less tendency than the fungus or medullary to involve different parts of the body together, and is slower in its march to its final termination. Hence the disease affords more time for the trial of calomel and opium, with

leeches, expurgating lotions, and the permanent pessary, but, as Sir Ashley Cooper rightly adds, great care must be taken not to do for the operation of castration so long, as to let the disease implicate the spermatic vessel, or a tumour to be formed in the gland.—(*On the Structure, &c., of the Testis*, p. 152–153.)

Neuralgia of the Testicle. *Testicular Testicle.*—By these expressions is signified a highly sensitive and exceedingly painful affection of the part, generally unaccompanied by any swelling, or other obvious change in it. The suffering is frequently of the most excruciating kind, and of long duration, though subject to occasional remissions. “A patient frequently complains of pain in the testicle when there is no disease in it. There is a state of the nerves of the part, which makes him feel pain in it, although there is no inflammation, and any other actual disease; and this is all that we mean when we talk of a neuralgic affection in this or any other part of the body.” You furnished an example of it in persons in whom a large calculus passed from the kidney to the bladder. As soon as the calculus has passed a little way down the ureter, the patient complains of pain in the testicle, which is at the same time frequently drawn up by the spasmodic action of the cremaster muscle into the groin. When you examine it, you find it of no other size, natural shape—at first not very tender, although exceedingly painful; in short, there is a painful affection of the testicle, dependent not on any disease of the organ itself, but on the influence which the calculus, as passing down the ureter, exercises on the spermatic plexus of nerves. Disease in the kidney will sometimes produce pain in the testicle, although there is no reason to believe that a calculus, or other solidness, has escaped from the kidney into the ureter.” (*Sir Benjamin Brodie's Lect. Med. Edin.*, vol. xii. p. 620.) From the observations delivered under the head of *Neuralgia*, the reader will perceive, that neuralgic affections may depend upon a great variety of circumstances, and especially on derangement of the general health. In the dissection of a testicle that has lost the loss of neuralgia, no change of structure can be found. In one instance which I attended, there was occasionally a little enlargement of the organ, though the most part remained free from all swelling or other manifest alteration. If the complaint be connected with functional disturbance of the liver or stomach, the chance of relief must depend upon the possibility of curing this primary affection. In many cases, which appear to be entirely nervous, or not associated with any other perceptible fault in the system, large doses of the sulphate of quinine, or of the carbonate of iron, may be prescribed; or, if the disease assume an intermitting type, and come on periodically, the *ferreus aperientis*. In some cases, the mixture of nuxvomica, opium, or hyoscyamus, brand with calomel, will answer best; and, if the liver be disordered, and the secretion of the skin checked, calomel, opium, and James's powder, should be tried. As frigid applications, leeches, ice-bag lotions, ice itself, or a plaster, one third of which consists of extract of belladonna, and two thirds of soap curate, or the venous sinistram, deserve to be particularly specified. For additional remarks relating to neuralgic affections, see *NEURALGIA*.

Atrophy, or wasting of the Testicle.—Sometimes this organ is either partially or completely

absorbed. This may happen from a blow or other injury which causes violent inflammation of the part, and disorganization of it. Obstruction of the vas deferens has been observed to be attended with a shrinking away of the testicle; a circumstance which would be expected from the necrosis of the functions of the organ being necessarily destroyed by such obstruction. Varicocele sometimes leads to atrophy of the testis; and sometimes the atrophy of the principal spermatic veins with a ligature or ligatures, adopted for the cure of varicocele, has been followed by this change in the testicle. Acute inflammation of the testicle from gonorrhoea, chronic enlargement of it from other causes, and especially scrofulous disease of the organ, may, in the end, lead to atrophy of it:—is the first case, possibly, in consequence of the vas deferens becoming sometimes permanently obstructed; but in the other two examples, no doubt, from disorganization of the testicle itself. The pressure of a large hernial swelling I have, often known occasion atrophy of the testicle; and the strong compression of the spermatic cord by a tumor would appear to be capable of producing the same consequence. Atrophy of the testicle was remarked by Baron Larrey to occur with remarkable frequency after the deep amputation of the back of the neck, received by the French soldiers in Egypt, in their conflicts with the Turks. Gonorrhea and excessive venery are believed to lead in some instances to atrophy of the testicle.

The inflammation and swelling of the testicles resulting from effusion of urine in the scrotum, and often accompanying testis is gonorrhea, will subside after the disease of the urethra has been cured. (*See J. Choquet, Pathologie Clin.*, p. 44.) Every surgeon of experience must have witnessed this fact.

The late Mr. Ramsden thought, that some sarcoles might be relieved by removing with heparina a supposed mercurial irritability of the testis, with which his theories led him to connect the origin of the complaint. (*See Pract. Obs. on Syphilis*, &c.) No doubt many chronic enlargements of the testicle have subsided during this treatment, especially when aided by calomel and other means; but a doubt may be entertained whether the benefit has any essential share in producing the benefit obtained. The practice, at all events, is not at present much adopted, though, on the first suspicion of it, many trials of it were made.—C.]

[Dr. Fancourt, of Philadelphia, has had occasion, very frequently, to remove scirrhus testis, and in all the cases attended with excruciating suffering, the disease has returned in the abdominal viscera or lumbic glands; and does the freedom of the vas deferens from the disease, afford any guarantee against its return, according to his experience.—Ramsd.]

[TETANUS. Dr. Alex. E. Hosack, of New York, has succeeded in curing two cases of tetanic tetanus by the free use of wine and brandy, and in one instance so completely was the patient saturated with these potations, that an attack of delirium tremens supervened, which was well characterized, and to this Dr. Hosack attributes the cure. In both cases the patients laboured under the most violent symptoms of the disease, and epistaxis was present. Dr. Deland was also in attendance and witnessed the favorable result.—Ramsd.]

[TISIA. Dr. J. C. Warren has cured the

this for tracheotomy four cases, in three of which he was successful. Dr. McClellan has repeatedly removed the iliac, lumbar, and femoral, tubercular abscesses.—*Reiser.*

[TONGUE. Dr. Thos. Harris, of Philadelphia, has twice extirpated the tongue for hypertrophy of that organ, and the patients have recovered. Dr. Minger, of the same city, has lately repeated the same operation with entire success. Dr. Minscy reports a similar operation in the *Amer. Jour.*, for 1835. In the same journal, for 1836, Dr. Dugan, of Louisiana, reports a case, in which he removed a greater portion of the tongue by ligature.—*Reiser.*]

[TONSILS. Dr. Alex. E. Brodie, of New York, was the first surgeon at America who removed the tonsils by excision, instead of the ligature, which had long been employed for the purpose. He published a paper on the subject in the *Amer. Jour.*, for 1827, which first called the attention of the profession to the use of the knife, which, under various modifications of instruments, is now universally used. Dr. Physick promised for many years the removal of the tonsils by the use of a double canula and iron wire, but the inconvenience often occasioned, by the troublesome sequelæ of this method, induced him to adopt excision as early as 1827. At first he used the scissors, but soon constructed an instrument for removing the tonsils or tonsils, which is described in the *Amer. Journal*, for 1827. Dr. Hirsch and Dr. Stinson, of New York, and Dr. Fajststock, of Boedapine, have each devised instruments for the purpose, and Dr. Gibson, of Philadelphia, describes one of his own in the late edition of his *Institutes and Practice of Surgery*. Different American surgeons and instrument-makers have mutually modified these instruments, and Mr. Thomson, of New York, belonging to the latter useful profession, has devised one which is very generally preferred to all others, as it serves to fulfil all the indications, and obviates all the dangers occasionally incident to the operation.

In the Philadelphia Med. Examiner, for 1828, Dr. John Mason Warren has a paper on enlargement of the tonsils, attended by certain deformities of the chest, which he has observed, particularly in children. His father, Dr. John C. Warren, has removed the tonsils by excision, 260 times. To guard against the hemorrhage which has occurred when the tincture has been used, he employs an instrument of his own, having an oval aperture to receive the tonsil, and a concave cutting blade is attached, which excises it readily, the pillars of the palate being forced back and protected. Necessities of these operations were rendered necessary by the difficulty of breathing, either occasioned by the enlarged tonsils, or co-existing and relieved by their removal. The next year for deafness or imperfect articulation.

Dr. Warren has closely investigated all his cases which were accessible, since the publication of Dr. Parish's paper on the Change of Voice, which he ascribes to the excision of the tonsils, never having before observed it, nor has he since found any corroborative evidence. He thinks that there must have been a wound in the pillars of the palate in each example as those of Dr. Parish, in which this change of voice occurred, and he remedies it to the satisfaction of the instrument which must have been employed in their excision.—*Reiser.*]

[TRACHEOTOMY. Since the note inserted

under the head of bronchiotomy was prepared, I have had occasion to perform this operation upon a child nine years old, who was near suffocation from the presence of a tamarind seed in the trachea. The parents, and other diagnostic symptoms, fully satisfied me of the presence of the foreign body, but on opening the trachea, inspection could not be detected. The opening was enlarged, and suffered to remain open half an hour, but nothing could be seen or felt of the seed, although the alarming symptoms subsided, and the child immediately relieved was obtained. I felt assured that the foreign body was lodged below the incision, perhaps at or near the bronchial bifurcation, and did not despair of yet accomplishing its removal. An obstinate cough continued, with intermitting fever, for several days, when a small portion of the seed came up by expectoration. But it was not until three weeks had elapsed that the main body of the tamarind seed came up, during a paroxysm of coughing, and the little patient is now convalescent.

In this case, although the operation did not immediately accomplish the object to which it was directed, yet there can be no doubt that it preserved the life of the patient; for at the time of its performance, the child could have survived but a short time. The decided improvement in the respiration which supervened upon the operation, and the absence of every bad symptom, said to be apprehended after bronchiotomy, satisfied us fully of the safety and utility of opening the trachea in dangerous cases of tracheitis from any cause. For although the opening was made of a crucial form, first by dividing the cartilage between the rings, and then by a longitudinal incision half an inch in length, yet, after leaving it open half an hour, it was closed by adhesive plaster, and in less than a week had entirely united; the air freely escaping at the opening, at intervals, during the first few hours.

Dr. Thompson, of Watrous, has performed this operation five times successfully, for the removal of foreign bodies and for croup. In the Med. Trans. of the State of New York, for 1813, he describes new instruments for this operation; and, indeed, for all operations upon the chest, including a stethoscope for keeping open the parts divided, and which he regards preferable to tubes.

The late Dr. Physick recommended this operation in the treatment of hydrophobia, as long ago as 1802, in a paper published in the *New York Med. Repos.* for that year. He was led to make this suggestion from observing, in a fatal case, that the spasmodic contraction of the muscles of the glottis kept the patient suffering for days with affable hoarseness of impending asphyxiation, respiration being at times wholly suspended. To this morbid condition he attributed the dread of water, supposed to be characteristic of hydrophobia. Whether he ever had the opportunity afterward of trying the efficacy of tracheotomy in such a case, I am not informed.

Dr. Mead has repeatedly performed this operation for the removal of extraneous substances from the trachea, or trachea, with uniform success, except when the foreign body has been lodged in one of the bronchi; and in one example which proved fatal, after this operation had been performed, a piece of the kernel of a walnut was found impacted in each bronchus.

A few months since, he removed a large black shawl pin, two inches in length, and having a

head nearly the size of a small marble, from the trachea of an infant eleven months old. It had been there fully eight years, and though its length presented great difficulty in its removal after getting hold of it, yet it ultimately succeeded, and the infant recovered.

As this operation is generally required in children, it is always difficult, especially as the emergency often demands its performance by candle-light. One thing is important to be remembered, viz., that for the success of tracheotomy, great caution is indispensably that it should be performed very slowly, and especially that the opening must not be made into the trachea until every drop of blood has ceased to flow. Without this precaution the child may perish from asphyxiation, even though only a very small quantity of blood may have entered the trachea. This catastrophe has resulted from this operation, and in one recent case occurred in this city, and in the hands of a reputable surgeon.—*Revue.*

[**TREPANING.** Dr. J. C. Warren, of Boston, has twice cured epilepsy by trepanning the skull. In one case of paralysis, for which he performed the same operation, he was unsuccessful. In the *British Med. and Surg. Journal*, he has published a case of neuralgia of the inferior maxillary nerve, for which he applied the trephine in the range of the lower jaw, and cured the disease by this operation.—*Revue.*]

[**TUMOURS.** Under this head I am permitted to add a highly interesting case of tumour of the neck, in which the operation for its removal was performed by Professor Alden March, of Albany, N. Y. And although this operation was unsuccessful, yet the cause of its failure was apparent, and ought to be known to the profession, that it may be avoided in future surgical wounds, in which the neck is to be involved. This operation was performed in August last, and the patient died on the table, from the introduction of the air into the cavity of the heart, through the external jugular.

The tumor was as large as a pint-bowl, occupying the left side of the neck, somewhat egg-shaped, having its largest extremity turned upwards, ascending on the side of the ear, so as to project it considerably, and inferiorly extending nearly to the clavicle.

The following are the report furnished of the operation:—The notes taken at the time:—

The first incision was commenced under the fold of the ear, and, pursuing a curvilinear direction, terminated in the sternal tubercle of the clavicle. A second incision was commenced in the line, and within an inch of the top of the tumor, and extending downwards in an opposite direction, terminating within an inch and a half of the sternum. A third was commenced upon the edge of the jaw, at an inch distant from the clavicle, and curved backwards and upwards, so as to form a right angle with the top of the first, and terminating at the posterior and superior portion of the tumor, the progress of the temporal vein.

The anterior flap was raised and turned over the larynx which exposed the surgical throat, inasmuch as the muscular fibres of the pharynx, and oesophagus were obliterated. The trachea was divided near the anterior margin of the sternohyoides, thus leaving the extent of nearly two inches, which exposed the muscular fibres of the sternohyoides. In the angle formed by these and the lower and anterior portion of the internal

muscle, the carotid artery was exposed and secured with two ligatures.

The next step in the operation was to separate the upper part of the tumor from the base of the jaw, the submaxillary and parotid glands, both of which were found to be in a perfectly natural and healthy state. At the point where the internal or facial artery passes through the submaxillary gland, it was divided, or a large branch of it. It died quite freely, although the collapse could not just be observed. This branch must have derived its blood from the internal carotid of the opposite side, by the way of the circle of Willis, by the vein, or by the superior thyroid of the opposite side, or perhaps from these several sources. This and the carotid were the only arteries which were secured by ligatures.

The next step in the operation was to dissect the posterior flap from the surface of the tumor, when it was found that the muscular fibres of the sternohyoid-muscles were completely obliterated over the centre of the tumor, it reduced to a mere tendinous fasciculus. The dissection was then directed to detaching the tumor from above and below, of course dividing the chief branches of the carotid, as well as the trunk, the pneumogastric nerve, and the great internal jugular. At this period of the dissection the tumor became loose, and an immediate and successful completion of the operation was confidently anticipated. But while carefully dissecting at the lower part of the attachment of the tumor, the external jugular vein was divided very near the point at which it unites with the internal jugular. At this moment a phenomenon occurred which was most alarming. It was the issue of a strange column of air, as though the trachea or cavity of the thorax had been cut into, and seemed to threaten the instant dissolution of the patient; a noise resembling the sudden pouring a liquid from a pump-bottle. The patient was instantly seized with tremors and convulsions, became paleless, the lips turned livid, froth at the mouth, and the pupils dilated to the greatest possible extent. The moment the occurrence happened, the finger was placed on the mouth of the wounded vein, and the operation being suspended, the patient seemed to revive from the effects of diffused air, and partially relaxed. The operation was soon resumed, and very soon completed. The patient, however, expired without a struggle before he could be removed from the operating table.

That this patient died by the introduction of air into the cavity of the heart, there can be little doubt, and this fatal operation of the neck should teach us the imminent danger of opening veins in the vicinity of the heart; and the knowledge of this danger may save many lives, which might otherwise be lost by a surgeon's mistake. It is unfortunate that the case reported by M. Dupuytren, of a similar operation with the *facial* vessel, has not been noticed in our medical works, and still greater cautions might have been used in this case. Dr. March informs me, that Professor Stevens, of this city, had well nigh lost a patient from the same cause, while operating on the neck; and Professor Morton had in similar an operation in consequence of this occurrence the convulsions were so alarming. This point, however, as well as that of Professor Brown, is covered.

Dr. March, the operator in the foregoing case here detailed, had since tried some experi-

ments on inferior animals, and among others, he introduced a blow-pipe into the jugular of a cat, and a single puff of the breath resulted in convulsions and death; and on dissection, the right side of the heart and larger veins were found filled with air. His experiments on this subject may be of the highest practical importance; and the explanation of the remarkable phenomena which followed the wounding of the vein in this and other cases, is a physiological problem, the solution of which, if accomplished, will be of the deepest interest to the profession and to humanity.

Dr. J. C. Warren has published an invaluable work on Tumours, which, at point of variety of pathological and surgical information on this topic, is superior to any other in the English language. This distinguished surgeon has twice removed the parotid gland, and in twelve cases dissected out lymphatic glands from the parotid region. He has removed forty-four submaxillary glands, two sublingual; and twice has extirpated one half of the thyroid gland. He has also successfully removed four tumours from the vaginocervical region.

Dr. G. W. Norris, of Philadelphia, relates an interesting case of protruding tumour in the head of the tibia, in which the femoral artery was tied without permanent result. For this case, and an accurate account of the pathological appearances, see *Amer. Journal*, No. 50, p. 283.

Dr. A. U. Stevens, of New York, has published a clinical lecture on the operative surgery of tumours, abounding in discriminating precepts of practical character, the merit of his extensive opportunities in public and private practice, and of his untiring success in this department of surgery. His two rules for guidance in the extirpation of solid tumours, which he very properly urges in this lecture, should ever be present in the mind of the young surgeon, viz.:—1st. Cut down to the tumour before its dissection is commenced; and, 2d. Remove the whole of the tumour and nothing more. In no department of the art is there more blundering surgery, and more culpable mal-practice, than in the removal of tumours by surgeons who have failed to learn, or neglected to observe these rules. By adopting the first rule, I have seen a tumour removed from the axillary region, and the plexus of nerves, as also the axillary vessels, artery, and vein, were completely exposed, while, by keeping close to the tumour they were all saved, though in intimate proximity, and no secondary hæmorrhage followed. The surgical union to perform such operations quickly cannot be so highly regulated, and tumours, especially, should never be extirpated in a hurry, for that which is well done, is soon enough done. Dr. Stevens has never taken up the carotid artery in the removal of tumours from the neck, and doubts if it is ever necessary.

By observing his rules, he has removed a large tumour beneath the mastoid muscle, which contained the sixth pair of nerves in one part, and the common carotid artery, the internal jugular vein, the p. vagin., and œsophagus in another part, without wounding either of these important structures. In several instances he has exposed the important nerves and blood-vessels bare, except covered by their sheath from the styloid to a point above the bifurcation of the carotid artery, and has never known secondary hæmorrhage or oblique to follow, the sheath of these vessels and nerves being sufficient for their sustenance.

Dr. Geo. McClellan, of Philadelphia, has removed the entire parotid gland nine times successfully, and in a majority of the cases the patients have had no return of the disease. He secures the hæmorrhage by tying the external carotid, under the digastricus, and in the course of the operation has found it necessary to tie the internal maxillary and the temporal. He tied the external carotid twice in three cases, but does not think it either necessary or expedient. He has removed parts of this gland in mutilated cases, when involved in tumours. He has five times removed one half of the thyroid gland, and in one case removed this gland entirely. In this instance, after tying both the superior and inferior thyroid arteries on both sides, he restrained the oozing of blood by the use of six of Hall's vessels, one just being placed upon the spine, and the other over the vocal, and relying upon the spring of the instruments for compression, which he finds does not impede respiration.

Dr. J. Mosen Warren has followed the example of his illustrious father in excising innumerable tumours, and with the like success. He has removed four large tumours from the neck; two large submaxillary glands, and two large tumours from the groin, which closely resembled hernia in their form and locality. In all these cases the operations resulted happily.

Dr. Mott and Bell, of New York, Dr. N. R. Smith, of Baltimore, Dr. Mossey, of Cincinnati, Dr. Warren, of Boston, and many other surgeons in America, have successfully removed tumours including in their structure the entire parotid gland. But to Dr. McClellan, of Philadelphia, belongs the merit of being the first surgeon in the United States to perform this operation, which he did in 1825. His patient, Dr. Graham, is now living in New York, and in excellent health. Since this operation, he has visited Europe, and enlarged himself in the examination of Sir Astley Cooper and Mr. Abernethy, both of whom were satisfied that the whole gland was removed.

Some doubts have been expressed as to the practicability of the removal of this gland, particularly by Dr. Gibson, of Philadelphia, who insists that it is a physical impossibility; and of course he doubts the accuracy of the reports of surgeons who have claimed success in this operation, whether among themselves or the world.

The evidence, however, must be regarded as conclusive, that in some cases the entire parotid has been removed, as in Dr. McClellan's first case, already alluded to. And yet there can be little doubt that in many of the cases reported as extirpation of the parotid, only a portion of the gland has been removed, while in others the tumours extirpated, though occupying the parotid region, have not involved this gland, and these are the cases which have furnished ground for skepticism in relation to others in which there can be no rational doubt. The case of Mr. Bell, as reported in his work on Tumours, is even more than doubtful, and on this case it is that Dr. Gibson predicates his opinion, that the operation is impossible.

That tumours of the lymphatic glands, superficial to the parotid, do often fill the parotid region is now well ascertained, and in many cases, by their gradual growth and pressure, they may even obliterate the parotid gland, cause its entire absorption, and completely occupy its situation. The removal of such tumours, extending deeply behind the jaw and filling the mouth to

cality acquired by the parotid in the normal condition, may be heretofore mistaken by the surgeon for the extirpation of this gland. And, indeed, that such is the case in several of the instances reported, is manifest from the fact that the hemorrhage has been considerable, and the external carotid has not been considered in the operation; this, with other large vessels and nerves, having been obliterated by the pressure of the tumor. The thoracic anatomy, in the displacement of the parts by tumors, often throws great obscurity upon such cases. The history of the disease, its obvious consequences upon the parotid itself, and the repair in such cases retaining the locality and configuration of the gland, and suspending or disturbing its function from the beginning: all these circumstances are essential to a true diagnosis. And it is only in such examples that any surgeon can demonstrate that he has extirpated this gland, even after removing a tumor from its seat. Dr. Warren, in his work on Tumors, distinctly recognizes this distinction.

Dr. N. K. Smith, of Baltimore is of opinion that tumors composed exclusively of the parotid gland, though commencing deep behind the ramus of the jaw, do nevertheless sometimes escape from the confined situation; and as the superficial structure of the gland and its facial portion become involved and changed, the whole diseased gland protrudes, elongating the vessels and other posterior attachments, so that it finally becomes peduncled. In these cases he thinks the removal of the entire parotid is a high operation, with great facility and without danger. In such circumstances he has removed the entire thyroid gland, and found the opposite and inferior arteries so elongated by the peduncled tumor, that they have scarcely required the ligature, the gland being nearly detached from its normal attachments. Under such circumstances the operation of removing the entire parotid or thyroid gland would involve neither difficulty nor hazard.

Professor Parker, of New York, has reported in the New York Med. Gaz., for Jan. 1842, a highly interesting case of cystic tumor in the hamula of a woman, occurring during lactation. "It was of enormous size, and he punctured it with a trepan and drew off three quarts of milk. The operation was repeated twice afterward. It appeared to have originated from a closure of some of the lactiferous ducts. The same surgeon has removed two cystic tumors of enormous structure. In each case the immense size of considerable size, not situated upon the ramus of a young lady. The cysts being opened, their contents were found to be of the consistency and appearance of chalk.

Dr. Alex. E. Mack has succeeded in curing scrophulous tumors of the parotid gland by applying a ligature to the external carotid. Two of his cases, under my own observation in this city, have been entirely removed by absorption, which commenced immediately after the ligation of this artery, and rapidly progressed until every vestige of the tumors had disappeared, though they were highly distending by reason of their great size. A third case is now under treatment, the operation having been performed, and the absorption having visibly commenced.

His success would seem to encourage a preference being given to this comparatively simple operation, instead of the hazardous and formidable methods of excision or extirpation of the gland. It might with propriety be always re-

sorted to first, and time enough elapse to ascertain its effect before extirpation be attempted. See Gibson's Surgery, last edition, and New York Lancet for 1842.

Dr. Albert Goldsmith, of New York, removed the parotid gland seven years since for an enormous hypertrophy of that structure, and the disease has never returned. By keeping close to the tumor he avoided all the large vessels, and occasioned few no ligature, and the hemorrhage was inconsiderable.

Dr. W. C. Wallace, an eminent surgeon of New York, has extirpated the faciohyal gland for an enormous tumor occupying this situation, and which had attained an enormous size. The patient recovered, and this far there has been no return of the disease.

On the 29th of April, 1842, Dr. Allen removed an adipose sarcoma of a deep nature, weighing about three pounds, from the axilla of a boy named Hancock, aged two and a half years. The tumor first made its appearance two years ago, at the external axillary ring, simulating the character and locality in the region of the existence of a hernia. On rising down, the tumor was found to be situated in the walls of the scrotum, between the testes and the tunica vaginalis, and so closely connected to the cord, as high as the pillars of the external ring, as to form a groove for the spermatic. The weight loaded by the funicular, and the boy retained large well.

Dr. Mead has successfully removed the parotid gland twice; in one instance, for inclusion of this structure, being the presentation of the external carotid. The disease, however, returned in other parts of the body, and ultimately destroyed the patient. He contends in the opinion, that this gland is not very frequently the subject of disease, although occasionally found, as in this example. The lymphatic gland, situated in the parotid, is much more frequently the seat of scrophulous and other tumors. He has frequently removed this gland under such circumstances, and in two instances it had become as large as two fists. In these cases, as he found the parotid partially enveloped by the compression, so as to leave the ramus of the posterior exposed, when the tumor is removed, and he has often seen the portion of the parotid remaining in a perfectly natural state. These cases are often confounded with tumors of the parotid, and are removed successfully, when the operation is supposed to include the parotid gland. So also with tumors of the axillary glands, the removal of which is easily effected, as Dr. Mead has found in numerous instances.

In one case, he found an enlarged tumor, containing a thin fluid and being enclosed within the parotid gland; this was subjected to three or four times its size. On tearing the tumor away, he found its aspect to be perfectly normal, which led him to cut into it, when the sac presented itself in the body of the gland, surrounded by its healthy structure. This being removed, the patient readily recovered. The young surgeon should here learn, that when the structure of the gland is normal, he should cut into it instead of attempting its removal. Dr. Mead has removed the sub-maxillary gland in a patient in whom it had reached the size of the fist, and the tumor was of scrophulous hardness and elevated. In discharging tumors of the thyroid gland, he has noted that the superior thyroid artery, and several branches of the inferior, with

excised himself, and very considerably thereby followed the operation. In one of these cases the sufferings of the patient, by the enormous magnitude of the tumor, became so great, that at his urgent solicitation, Dr. Moffat was induced to excise the whole gland, after its dangers were fully explained. The operation was performed, and the patient died from secondary hemorrhage. The tumor weighed six pounds.

In Professor Gross's late work on Pathological Anatomy, vol. ii. p. 170, some account is given of a tumor of the prostate gland, which had attained an enormous size, and which seems to have consisted of a fatty degeneration of that organ. Its extirpation was successfully performed by Professor Parker, now of the College of Physicians and Surgeons, in New York, and the patient completely recovered, with the exception of the partial paralysis of the side of the face. In this case the removal of the entire prostate was necessary, involving the division of the duct of Siem, and the prostatic duct, and

requiring the ligation of the external carotid and three other arteries. The excision exposed the stylized process of the temporal bone and its muscles, and yet the wound granulated kindly, the ligatures coming away the fourth day, and the patient was discharged cured in four weeks from the date of the operation. The tumor is preserved in the museum of the College, in New York.

Professor N. B. Smith, of Baltimore, reports a highly interesting case of the successful removal of a tumor involving the prostatic gland, accompanied with cerebral symptoms, and his personal testimony to the removal of the entire prostatic gland, by Professor McClintock, of Philadelphia, in an operation of which he witnessed the performance. He also mentions the same method as due to the late Professor Davidge, of Baltimore, Professor N. Smith, of New Haven, and Professor Bailey, of Kentucky.

Dr. J. Randall also extirpated the prostate in 1838, with entire success. (See *Amer. Jour.*, for 1839.—*Edin.*)

U.

URETHRA. Before speaking of accommodations of the urethra, I will request the reader's attention to a few points of surgical anatomy, very necessary to be well understood by all who have occasion to pass instruments into this passage. From certain facts, specified by M. Malgaigne, it appears, that when the penis is lifted up, but not extended, a catheter has only to pass at most seven French inches and a half, when it will enter the bladder, and that a catheter, which is allowed to remain, will project at least as much into the bladder, if it has passed to the extent of seven French inches. (See also *Vopros. Anat. Chir.*, t. xxi. p. 234, 8vo, Paris, 1838.) The length of the prostatic portion of the urethra is variously estimated, from six to ten lines, (Malgaigne,) twelve to fifteen, (Dumas,) eight to eleven, (Ligot,) and that of the membranous, or muscular portion, from five to eight lines, (Malgaigne,) nine to ten, (Dumas,) and seven to eleven, (Ligot.) Its extent is not the same superiorly as inferiorly. Here it is very short, limited in front by the posterior extremity of the bulb, and behind by the prostate; so that superiorly its length is about an inch, and inferiorly, four or five lines. (Benjamin Phillips, *On the Urethra*, &c., p. 11.)

The spongy portion is subject to the greatest variation, and is the only part of the urethra, in which the different positions and the extension of the penis make a change. In the relaxed state of the organ, there is an angle in the spongy portion of the canal, corresponding to one of about 45°, which is effaced during an erection. reckoning from beneath the symphysis of the pubes, the two other portions of the urethra ascend obliquely backwards, so that the vertical surface of this canal is three or four lines above the level of the arch of the pubes, and one inch behind the symphysis. M. Malgaigne also states, that when a straight catheter had been introduced into the bladder of a dead subject, laid out upon a table, the instrument described, in relation to the grooved and the axis of the body, an angle of about 45°. When the penis is raised, as during an erection, the angle in the

spongy portion is effaced; but the curve in the membranous and prostatic parts remains unaffected.

The direction of the canal, when the organ is erect, has been usually compared to the letter S; and Mr. Benjamin Phillips believes, that this may be nearly correct when the bladder and rectum are distended;—but when the penis is placed against the abdomen, there is found only one curve, and this almost disappears when the bladder and rectum are undistended. If we place the penis in a direction nearly at right angles with the ideal axis of the body, and look at the urethra in that position at its course within its not bonyed the symphysis of the pubes, it will be seen that it forms a curve, which presents its convexity inferiorly; and that, after arriving in front of the pubes, the direction of the canal presents a straight line. When the corpora cavernosa are healthy, we may remove all curvature with the exception of the first. In order to attain this end, M. Amussat has recommended, that the position of the penis should be such as to form with the axis of the thigh (the patient being in the erect position) an angle of 30° to 45° (*On the Urethra*, M. Dumas, &c., p. 12.)

The urethra, then, is far from being straight; but it may be rendered so. The urethra of the urethra being soft and yielding, it is capable of being dilated to a certain degree. If its lower side then be depressed, by means of any solid instrument, the lower part of the rest of the penis, and its upper side be brought by the same instrument below the symphysis of the pubes, the angle in the spongy portion, and the curve in the rest of the canal, must both be at once obliterated. But, in order that the rest of the penis may be thus depressed M. Malgaigne observes, that his suspensory ligament, which connects it to the symphysis of the pubes and to the lower arch, must be loose;—and that, when the penis is attached higher than usual, or the symphysis descends lower, greater difficulty is experienced in rendering the urethra straight. The same thing occurs when the prostate gland is in a state of

enlargement, which carries the vesical orifice of the urethra above its natural level. This is well represented in two plates of Stanley's work on Lithotomy. In two subjects, having hypertrophy of the prostate, Mr. B. Phillips ascertained the level of the most dependent portion of the prostatic part of the urethra to be from six to seven lines and a half below the level of the vesical orifice of the canal; whereas, in healthy subjects, he found it to be only from three to five. (Op. cit., p. 18.) The spongy is the most dilatable portion of the urethra; but as any yielding of it upwards is prevented by the corpora cavernosa, between which it is lodged, the dilatation is almost entirely at the expense of its lower side, and admits of being carried to the greatest degree at the bulb, where the spongy substance is most abundant. At this point, corresponding to the almost directly oblique symphysis, the canal suddenly becomes vertical, as at the commencement of its lowermost portion. Afterwards, it enlarges again in its prostatic part, but here its floor has two lateral grooves in it, occasioned by the projection of the verumontanum in the middle. At this instance of the bulbo, there is also on the same lower side of the canal a transverse prominence, formed by the substance of the prostate gland, and a few fibres of the sphincter, which prominence is termed by M. Arnaud the *pyramide*. The upper side of the urethra being everywhere smooth and firm, presents no obstacle of this kind.

Hence it is manifest, that when the beak of a catheter is inclined against the lower side of the urethra, there are two stoppages, not mere mechanical obstructions, and met with even in the dead subject; but there are two others which exist only in the living body, and which depend upon the contraction of the sphincter vesicæ. Such, according to M. Malgaigne, is the urethra of the adult male subject. In the child, the difficulties are less; the penis is less enlarged; the symphysis of the pubes does not descend so far; the prostate is equally flat; the corpus spongiosum is but little developed; and the lower side of the urethra is, as firm, that, until the age of twelve or fifteen, scarcely any obstacle is felt in the whole course of the canal. In an old man the reverse is the case: the corpus spongiosum, which is lower, again of being depressed further towards the bulb; the prostate gland is frequently enlarged; and what M. Arnaud calls the *pyramide* more strongly marked. From all the foregoing circumstances, it follows, that, *ceteris paribus*, it is easier to insert, or pass an instrument into the bladder of a child, than an adult, and an adult, than an old person. (See J. F. Malgaigne, *Manuel de M. d'Opér.*, p. 670, vol. 3; also, Paris, 1833.) In children, however, for reasons caused by allusion to, and partly elucidated by Mr. B. Phillips, the urethra is wider except. (On the Urethra, &c., p. 10.) The male urethra being long and narrow, having above the angle and curve in it above described, and being surrounded by the prostate gland, and other parts whose diseased states are liable to interrupt the freedom of this canal, we cannot be surprised at the fact, that it is subject to more tumours, as well as far more serious diseases, than the short, capacious, and simple urethra of the female. Thus, as an able surgeon remarks, "a mechanical obstruction to the flow of urine through the male urethra may arise in various ways. There may be an enlargement of the

prostate gland, by which one extremity of the urethra is expanded; or always in the perineum; or one of the mucous follicles may be inflamed, and converted into a solid tumour; and any one of these, as well as many other causes, may operate so as to produce the effect. The most common cause of difficult insertion, however, is a contraction of structure of the urethra itself." (See Benj. Brodie, *On Dis. of the Urinary Organs*, p. 2, vol. 2.)

Mr. Benjamin Phillips does not concur in the opinion that the membranous portion of the urethra is the most frequent seat of false passages, and he maintains that it possesses much solidity. "False passages (he observes) are less frequent here, than in the bulbous portion of the canal. (See also Velpeau, *Med. Opér.*, t. iii., p. 386.) The reason of this must be immediately evident: false passages are readily made in consequence of the difficulty experienced in the entrance to pass an instrument through the strictured portion of the tube. Stricture is most frequently seated at the point of junction between the bulbous and membranous portions of the canal; consequently the false passages will be usually anterior to this latter point." (On the Urethra, &c. *loc. cit.*, p. 10. See also Velpeau, *loc. cit.*, p. 310.) "Thus it is obvious that a narrow, a not deep, an oblique, and an anterior, or an oblique in direction, and its perforation indications."

In the articles CATHETER, and URETHRA, RESECTION, &c., I have noticed the advice of Sir Benjamin Brodie, and of M. Velpeau, to keep the back of the catheter, stiff, or rigid, against the upper side of the urethra. "This side of the urethra, forming the concave margin of the segment of a circle, lies in this very aspect, glides then the other, and less disposed to wrinkle. Having no recreation, and being closely adherent to the lower surface of the penis, it presents in its spongy part great regularity, and is so strong as not to be in danger of injury from the catheter." There is, however, as M. Velpeau explains, a small portion of the upper side of the urethra almost naked, just in front of the symphysis, where the corpora cavernosa diverge from the bulb to be inserted into the rank of the scrotum and os penis; and when the beak of the instrument, if carelessly pushed on, may do mischief. (See Velpeau, *Med. Opér.*, t. iii., p. 387.)

This subject has not been overlooked by Mr. Benjamin Phillips. "In introducing an instrument into the urethra or bladder, (says he,) it is necessary to recollect, that the two opposite portions of the urethra—the superior and inferior—differ singularly as to their conformation, and that we cannot indifferently follow the one or the other with the beak of an instrument. The inferior portion is yielding; the superior along the penis not at the height of the scrotum, are beneath the pubic symphysis, is supported by nothing solid. In sliding along the canal, the beak of the sound may easily push down the lining membrane of the urethra; or, sliding its surface, we meet at intervals with injections of the membrane, resulting from its flatness, which occasionally have a tendency to arrest the progress of the instrument. Some richness of mucous follicles, and, among others, those of the glands of Cowper, are, according to general opinion, susceptible of recurring and arresting the beak of a sound, especially if it be of a small size." Lastly, at the level of the bulb, and in front of the entrance of the neck of the blad-

der, on the sides of the verumontanum, these exist on the inferior surface marked depressions, the sides of which are directed towards the external orifice of the urethra; against these the back of the sound passes, and by them is occasionally prevented from making further progress.

"If we examine by means of dissecting (artificially made) false passages formed in the urethra during life, or after death, in subjects labouring of catarrhus, we find, that they are produced by the rupture of the inferior crypts of this canal, and that the greater number of these passages exist either at the situation of the depression I have pointed out, or at the bulb. The disposition of the superior part of the urethra is infinitely more favourable, as a conductor for instruments, than the inferior. Sustained in front by the corpus cavernosum, and behind by the pubic symphysis, it presents great firmness; and we find only logarithmic dilatations, which are removed by the dissection produced by the instrument; and no obstacle is here presented to its progress. No depression exists here under ordinary circumstances. There is no projection of the prostate into this portion of the tube; neither do we find many folds, either isolated or grouped; nor any considerable callosities." (On the Urethra, &c. p. 129.) For additional remarks, see CATARRH, and URETHRITIS, &c.—C.

[Dr. Alex. E. Bosack, of New York, has called the attention of the profession to a peculiar affection of the female urethra, consisting of small tumours of a solid red colour situated within the urethra, and covered by the delicate lining membrane of the urethra, and demanding surgery for their relief. He describes them as exquisitely sensitive, and bleeding upon the slightest touch.]

They resemble a split pea, varying from that to the size of a small kidney bean, and are placed upright in such a manner as to break the flow of urine. The patient does not complain of the pain of urinating at her greatest distress, for it is not to be compared to that caused by exertion, or from contact of the dress, which is frequently excruciating.

These tumours are attached usually to the margin of the urethra, from which they can be readily snipped off with the scissors; they are pale, however, to return, and the margin of the urethra assumes a fungoid appearance, with the same highly organized structure. In some instances it appeared as if the lining membrane had shot out like a fungus, or was pedicled, under which circumstances the doctor is in the habit of excising a portion of the urethra, say from half an inch to an inch from the external orifice.

The steps of the operation consist in first measuring the length of the urethra by the introduction of a slender catheter, and making it the instant the urine begins to flow, the finger-experience is then imposed with the point of Mucous and drawn out.

The urethra is next circumcised with a knife, carrying on the dissection until you arrive at sound structure, when you make a transverse section of the whole. The hæmorrhage at this moment is excessive, but by pressure it is always arrested. The patient is usually troubled with retention of urine, making it necessary to have the water drawn off. This inconvenience may be obviated by leaving up a catheter in the

bladder for the first day or two after the operation.

This disease is spoken of by Morgagni in 1761, afterwards by Mr. Hughes, in Gloucestershire, in 1769, and also by Mr. Wardrop in the London Lancet, vol. 12; by Boyer in his Surgery, Sharp, Winslow, and Astuc's Chancery, and Dubois, Malacou du Châpelle, Rosenmüller, Vogel, Kuhlbrandt, and Præschke.

Dr. A. E. Bosack arrives at the following conclusions respecting this disease:—

First, that the disease is characterized by peculiar symptoms. Second, that it is not confined to any age. Third, that it is unaccompanied with discharge, and the parts are found to be normal. Fourth, that in order to prevent a return of the disease it is better to remove at once the external portion of the urethra, including the tumour. Fifth, that it is a complaint of slow growth, and does not attain to any great size, for in six instances, yet recorded, we find it not enlarged to more, but it been found larger than a small cherry.

Dr. Parker, of New York, has lately performed the operation of excising these tumours from the female urethra with success.—*Remedy.*

URETHROPLASTIC. The application of the autoplasmic method to the cure of fistula, fœces, and ruptures of the urethra, has been successfully made by Drs. Blott, Maitre, Demoult, Mucifin, Bancelin, and many other American surgeons.—*Remedy.*

URINARY CALCULI. A highly interesting case has lately fallen under my own observation, in which several of a kindred calculi have passed at different periods, through the urethra, varying in size from that of the head of a pin to that of a large sized grain of coffee. Seventy-three of these calculi are now in my possession; and as the patients under my personal observation, and more are passing every week, I can vouch for the facts here recorded, and shall report to the profession the progress and the result of the case in one of our periodicals.

The colour of these calculi is a yellowish brown, very smooth on their surface, and for the most part have a convexity on one side, and a concavity on the other; which, with some gain, may be accurately fitted one to the other, in the same order and relation in which they may be supposed to lie when in situ.

These calculi resemble very much those little concretions which are so often discharged from the bladder, and are little to be mistaken for these. On analysis, however, they are found to contain only phosphoric lime, without a particle of uric acid or ammonia. The valuable paper of Dr. Williams, in the *Philosophical Transactions* for 1827, has been, or with this test, by which to distinguish the calculi of the prostate gland from those of the bladder and kidneys; and by this and other criteria, there can be little doubt but the conclusion is the same here exhibited in the present case; whereas, so fast as they are discharged, they get back into the bladder, or forward into the urethra; and then pass off with the urine.

The history of this case is highly important, and from the patient I collect the following facts:—He had been of a hale, vigorous constitution, without any symptoms of this affection, until about four years since, when he was 64 years of age. He was then attacked suddenly by a suppression of urine; frequent supplication, but no ability, to empty the bladder; pain in

exhausting, as to disable him from his work and even walking. He at last resorted to Hahnemann, and by the advice of his physician, took medicaments of various kinds made of rhubarb; the disease being supposed to have originated from the young water treatment used. Soon after this excruciating tertoid came on, while expecting aid to a great extent, with the hope of finding relief by this means, he observed for the first time, that whenever the urine flowed, small calcareous concretions of a yellowish colour, of the shape and size of rufous seeds, passed through the urethra, having collected a tea-spoonful of these little stones, he submitted them to a physician for examination; for when he was sent to a distinguished surgeon at this city, that he might oblige the operation of cauterizing. The wound having been introduced, and the presence of calculi having been detected, he was told that the operation of lithotomy could alone afford him any relief.

From his advanced age, he declined to submit to the operation, and gave himself up to a lingering death. As, however, no relief was obtained from the diuretics or diaphoretics which he had been so long using, and as he began to feel that the gut was doing positive injury, he resolved to discontinue the use of them all, and began to drink pump-water, from which he had been deprived by medical advice, and then, as he expresses it, "lived in the land for him or death."

In about three weeks from this time in which he thus gave up all medical treatment and drank freely of cold pump-water, he observed a small stone to drop into the urine, and in a few days another; each affording him some relief. Since that time, which is now a little more than eighteen months, he has passed all these, and many more which have not been preserved. He says that one passes every four or five days, and sometimes two at once, and he is conscious of the passage of each, although the pain is very slight. Since these calculi have been passing, he has been rapidly becoming his health and bodily strength; and from a spectacle of emaciation, he is now a strong, robust man, and at his age has extraordinary health. He has no difficulty in passing his urine, except some times when a momentary interruption occurs to the stream, by one of the stones passing into the urethra; when it is soon forced out with very little inconvenience.

He is impressed with the belief that there are fragments of a large calculus in his bladder, which was felt by the surgeon, and that since he ceased to trust in lithotomy, it has been continuously broken, and that he is now compensated by supernatural agency. He is perfectly happy under his condition; and the prospect of dissolving his first fine view of the subject, or convincing him that natural causes will account for the comfort he enjoys, is exceedingly questionable.

But while we leave the patient himself undisturbed in the enjoyment of his health, the medical philosopher cannot fail to despair in the progress of this case, as portrayed by the patient, and in the results of which he is now so glibly given, details preserving more most important and interesting features, which may be improved for practical purposes.

That these calcareous deposits have never been larger than they now are is clear from the smooth surface, and from their peculiar organi-

zation. That they did not originate in the bladder or kidneys may be deduced from the fact already named, that they do not contain an atom of the lithic acid. And that they consist at all in the bladder in this quantity, any length of time is impossible, from the fact that so soon as one of them gets into the bladder, it produces uneasiness, and it is dislodged, when the relief seems to be entire.

The probability is, that when he was visited by the surgeon, one or more of these calculi had passed into the bladder from the prostate gland, in which they were imbedded, either in the enlarged cells of the gland, or coagulated, as they are sometimes found. There were but a few, the number being the most probable, therefore, they passed one or two at a time into the bladder, and so on through the urethra.

Had this patient submitted to the operation of lithotomy, and the calculi been removed, it could be readily perceived that no permanent urinary secretion would have been obtained, as to remove them from the body of the prostate is altogether impracticable. It is highly probable, therefore, that his refusal to submit to lithotomy has saved his life, although any opinion would be liable to give the same opinion under similar circumstances. May we not surely presume, that many of the failures occurring in lithotomy occur under similar circumstances, the calculi originating in the prostate, and thence finding their way perpetually into the bladder?

In Marcet's valuable *Essay on Calculus Vesicæ*, much information on this subject will be found, together with a plate very accurately representing these calculi of the prostate gland. He states, that the symptoms are also marked for stone in the bladder; and if any of these calculi be discharged, their appearance is so similar to that of lithic concretions, that unless their chemical nature be ascertained, they will almost infallibly be mistaken for the species of calculus. He also presents an instance of a surgeon of the opposite kind, in the case of a young minister, who, while attended by one of the most eminent surgeons in London, passed a number of small brownish concretions, which were mistaken for calculi of the prostate, and the treatment was for some time instituted on that supposition. But upon subjecting these calculi to chemical analysis, he found them to consist of pure lithic acid; and upon an appropriate treatment being adopted, the symptoms were entirely disappeared.

Another form this affection, and requiring different treatment, a case may be mentioned which often occurs, in which the calculus, although formed in the kidney or bladder, becomes lodged in the prostate, in attempting to pass through the urethra. Sir Astley Cooper has recorded a case of this description, in which, upon attempting to introduce the catheter, he felt a grating sensation at the neck of the bladder; and so inclosing the finger into the rectum, calculi could be felt moving in a spot within the prostate, and sometimes passing could be heard as their surfaces were pressed together. It was proposed that a small incision should be made through the rectum into the prostate, for the purpose of extracting the calculus; but the patient would not consent. This gentleman died a few days after, and a few days after was found to contain a number of calculi; and this was the case with his kidneys, from which these came

existence had sometimes threatened, and were treated in their course.

Dr. W. Cutler, of Philadelphia, has a statistical account of cases in the Pennsylvania Hospital, in the *Amer. Journ. for 1828*, which is valuable and well to be referred to.

Professor Gibson has a valuable chapter on this subject in his late work. He mentions a singular variety of calculus found under the bladder by Dr. Physick, and since by Dr. Leakey, of Washington county, Pennsylvania. It closely resembled common plastering mortar, and consisted of both scales of calcareous matter and hair. In his own practice, Dr. G. removed a large stone by lithotomy from a boy four years old, in the centre of which was found the greater part of a needle, which had secured the nucleus for a calculus, which had only last assumed the gloss of a small stone.

The case of the late Chief Justice Marshall, upon whom Dr. Physick performed the lithotomy operation of lithotomy a few years ago, is in our respect unique, viz., the number of calculi found in the bladder, which he exceeded that ever before reported. The most remarkable fact on record is that in which six calculi were found in the bladder after death, but Dr. Physick extracted from the bladder of Chief Justice Marshall more than one thousand, varying from the size of a partridge shot to that of a bean, which were created, besides many which were lost. They were uniformly of an oval shape, and upon the end of each was a thick spot of the size of a pin's head. Notwithstanding the frequent introduction of the forceps and scoop, as well as the other precautions for completely draining the bladder, the venerable patient, who was of very advanced age, completely recovered, and for a number of years remained upon the bench he had so long honored in excellent health.

Dr. Sewall, of Washington, has recorded, in the *Boston Medical and Surgical Journal*, an extraordinary case of hemiparalytic calculus.

For the treatment of urinary calculi, Dr. Physick was in the practice of using the extract of hyalassac, (pisciberry,) in doses of a dessert-spoonful three times a day, with or without ten or fifteen drops of opium or turpentine. The Venice turpentine made into pills, to the extent of half a drachm in 24 hours, is recommended by Dr. Bevan, of Germantown. These and the like remedies are useful when the patient is suffering from a fit of the gravel, or in anticipation of its recurrence, and which for the most part is dependent on the passage of a calculus along the ureter.—*RATER.*

UTERUS, CANCER OF. The disease gradually first attacks the cervix, and especially the posterior lip or margin of the os uteri. In the beginning, the symptoms are attended with ambiguity, and cannot be discriminated with any degree of certainty from those arising from various other causes productive of irritation of the womb. Most frequently the disease is ushered in by irregularity of menstruation, a profuse bloody discharge, or a profuse leucorrhœa; together with an annoying sensation of tension, weight, and dragging pain in the lumbar and hypogastric regions, extending frequently to different points of the pelvis and high femoral bones to make water, urination; and finally, a burning pain in the cervix uteri. On examination, the portion of it towards the vagina is perceived to be either hardened on every point, or indurated in some places, and softened in

others. The os uteri is likewise indented, irregular, and half open. When pressure is made with the finger, a sanguine bloody matter is discharged.

The disease may continue in this state for several months, or even years; but, at length, the symptoms become aggravated; the dragging pains, which now affect not the groin and thigh, occur with increased violence; and the discharge becomes exceedingly fetid and red, mingled with bloody matter and clotted blood. Sometimes, as I have frequently noticed, profuse hemorrhages occur. At the same time, the constitutional impairment becomes more and more serious, and is accompanied by the anorexia, hectic, and the pallid sallow appearance of the countenance, so characteristic of organic disease. Ultimately death takes place, either suddenly, from profuse bleeding, or, as more usually happens, the patient dies hectic, in a state of hectic suffering.

If, in this advanced form of the disease, a post mortem examination is instituted, the portion of the uterus connected with the vagina is found enlarged, or more or less destroyed, and thick, or diffused masses, extend from this point within the cervix. The tumor, in upper portion of the vagina, is frequently much hardened; and the attention may even be attracted to the os uteri and bladder, so as to form new connections between one or even both these viscera and the vagina, and account for the involuntary discharge of urine and feces by the latter passage.

When the disease commences in the cavity of the cervix, the cervix remains for a long while unaffected, while the body of the womb enlarges in every direction, and may attain considerable magnitude. In such a case, the swelling is sometimes distinctly perceptible through the paries of the hypogastrium.

Cancer of the uterus may originate at any period after puberty, (Ciculus, *Bartholin's Chor.*, l. ii. c. 680.) but the time of life between the ages of 40 and 50, is that in which its commencement is most common. I have attended not less than three women, who died, relative to the age of 20; than the effects of the cancer of the womb. Cruveilhier observes, that from the age of 25 to that of 50 is the principal season for this cruel disease, though he has known one woman of the teens die of it, whose age was only 30; and has seen it in women as old as 80, 70, 60, and even 55. In University College Hospital, I lately had a case in a woman about 70, in whom it proved fatal about two years after its first detection. In this case, the disease had impeded the whole of the vagina and even the labia. The young woman, whom I attended in Great Ormond Street, for a cancerous womb, of which she died, had an aged mother, who had suffered severely from carcinoma of each breast; but had latterly been freed from the disease by a sloughing process, an event which is uncommon, but does now and then happen. (See *Cancer*.) Next to cancer of the breast, cancer of the womb is the form in which the disease most frequently presents itself. Sometimes the disease takes place in the womb and breast together; and Cruveilhier records an instance in which cancer was accompanied by a medullary tumour in the substance of the left hemisphere of the brain, so that, in the latter stages of the case, the patient was attacked

with osseous and hemiplegic. According to this distinguished pathological, however, notwithstanding the tendency of cancerous disease in general to affect the whole economy, by extending from the point first attacked, as from a centre, cancer of the womb is but rarely accompanied by this general implication of the system, and especially of the brain.

It appears also, from Cruveilhier's researches, that the vagina is as frequently the seat of cancer as the neck of the womb. "In anterior pages it is much more frequently attacked than its posterior; and hence it is rare to find instances in which the lower portion of the bladder does not participate in the disease." (*Ann. Pathol.*, iv. xiii, p. 6.)

Cruveilhier feels, that what he terms the smaller polycancerous cancer, is the most frequent of all the forms of cancer in which the uterus is liable. In this the uterus is transformed into a spongy texture, from which a cancerous substance, of gelid or fleshy consistence, may be compressed in the shape of small worms; so that, when this texture has been crushed by suitable preparation, a hollow cellular structure remains. Cruveilhier conceives, that he has made out the fact, that cancer of the uterus begins in the venous system. However this may be, he notices another fact, which is of greater importance to the practitioner, viz., that the lymphatic glands in the pelvis are almost constantly affected in cancer of the womb. He specifies in particular two, situated, one on the right and the other to the left, on the sides of the pelvis, on a level with the highest part of the ischio-anal foramen; these, he says, are often the only lymphatic glands implicated. The lumbar glands he finds less frequently diseased than the pelvic; and he states, that they may be enlarged and red without presenting any vestige of cancerous structure. "The uterine glands are only involved when the disease attacks the external uterus, and the orifice of the vagina. In only one dissection he found the cancerous substance in the thoracic duct, though he examined it at every opportunity; and, in another instance, he traced the same substance in many of the lymphatics, which proceeded from the diseased parts." (*Op. cit.*, iv. xviii.) In one case, described by Cruveilhier, one ovary was enormously dilated, and the corresponding kidney wasted. "The relationship the uterus with the lateral and superior part of the vagina, and with the lower part of the bladder, which is often implicated in cancer of the uterus, account for the impellment to the flow of the urine through the ureters, the lower portions of which are often surrounded by cancerous masses, which compress them. This compression may take place in so great a degree, that the lower part of the ureter is completely obliterated, and, what is remarkable, such compression does not produce the fatal consequences which theoretically might be expected. The urine dilates the ureter, (*vide* *loc. cit.*, p. 2, dg. 2.) which, at the same time that it becomes dilated, is lengthened and rendered tortuous or spiral, like a varicose vein. The pelvis and calices in their turn are also expanded, so as to acquire a considerable capacity. The kidney, compressed by the urine, notwithstanding in the dilated calices, gradually wastes away, and is converted into a mere shell, or husk of a pale yellow, having some resemblance in colour to the changed state of the kidney, known of late by the name of Bright's dis-

ease; and such atrophy may proceed so far that no urine can be secreted, or so little, that any sedulity may be easily prevented by absorption." The possibility of life continuing long, with an obstruction of both ureters, would be, however, a very different case from that described by Cruveilhier.

Gangrene, consequent to cancer of the womb, as found by Cruveilhier to be very common, sometimes destroying the cancerous structure, layer by layer, and, in other instances, attacking the whole mass of it. In both cases, the discharge becomes horribly fetid, and when the finger is withdrawn from the vagina, it brings away a bloody purid secretion, which Cruveilhier says can be compared to nothing more like it than the putrescence into which hospital gangrene transforms the textures invaded by it. This discharging may advance slowly or rapidly, a difference which has vast influence on the intensity and symptoms of the symptoms. When gangrene attacks the whole of the cancerous mass, and nearly annihilates it, the case might be mistaken for one of primary mortification; and in many examples, the cancerous state of the pelvic and lumbar absorbent glands is the only criterion of the gangrene having been produced by a cancerous affection of the uterus. (*Cruveilhier, Ann. Pathol.*, iv. xxv.)

As I have never seen more than palliative relief derived from medicines as local applications, in the treatment of true cancer of the womb, I shall need well long upon this part of the subject. So far as my experience goes, temporary relief is to be sought principally in the judicious employment of narcotics and purgatives as necessary requires, the hygienic position, rest in the hypogastric region in the early stage, isomentation, and frequent solution with tepid water, or decoction of poppies. I have not generally found the chloride of soda useful, nor any astringent injection, superior to cold water in the temporary relief afforded; but when the discharge is copious and exceedingly fetid, they may be tried. The tincture of iodine, the hydropic acid of potash, the tincture of mercury, the carbonate of iron, the liquor arsenicalis, the aqua haemorrhoidalis, and almost all the medicines specified in the article Cancer, I have examined, but without any permanent benefit.

Modern experience proves, however, that when cancer is rather extensive, is confined to the neck of the uterus, it will sometimes admit of being successfully removed by excision. The cervix uteri, in the healthy state, projects from three to six lines into the vagina; but M. Lisfranc has known it make no projection at all. The vagina around it is thin, and in contact, on one side, with the bladder, and, on the other, with the rectum; while upwards it is continuous with the proper substance of the uterus. The vagina may be detached from the cervix uteri to the extent of more than half an inch, without any risk of opening the callosities of the perineum which separates it from the bladder; but since the latter is now adhered very intimately to its anterior surface, it might then be reached by the instrument. Behind, the perineum not only covers the corresponding surface of the uterus, but also descends over the vagina, to form what M. Vrieseu terms the perineal excavation; so that, on this side, the knife, if carried with a softness, would meet the perineum. M. Vrieseu considers it erroneous then to say that there is a space of eight lines in

might be supposed that the operation just described must necessarily be of an extremely painful nature, and that troublesome hemorrhage would always occur. But no such consequences usually ensue; the drawing down of the organ being commonly effected by very slight efforts; and, as to pain, the patients hardly ever appear to experience any. The bleeding seldom exceeds one or two ounces. There is one consequence, however, which usually follows, and which, I need scarcely observe, requires to be extrinsically treated; I mean inflammation of the peritonæum. Whether this arises from the division of the portion of that membrane descending between the rectum and uterus, or from continuous sympathy, (as Hunter calls it,) or from an extension of the disease from the gynecymatous substance to the membrane covering of the uterus, is not easy to determine. The portion of the cervix removed is usually that which projects into the vagina, and so more; and it will, I imagine, be conceded, that when we consider the general extensibility of the organ, such a portion of it may be safely excised without impairing the important membrane in question; but I do not say that, on occasions where a portion of the body has been removed with the cervix, such an injury may not have been done; an operation which the practitioner should do his utmost to avoid." (See Dr. J. Brown's paper in *Edin. Journ. of Med. Science*, vol. vi. p. 21-27.)

In 1828, M. Lachapè had performed this operation on thirty-six individuals, as is stated, for cancer uteri, the recognition of which last declaration as a positive fact, I beg to observe, is a matter of great importance in determining the merits of the operation. Of the thirty-six patients thus operated upon, "thirty were then well, three dead, and three in progress of recovery. One female, operated on some years before, had since become pregnant, and recently given birth to twins. Lastly, at the Hôtel-Dieu, the entire uterus has been removed by M. Roux; and, in September last, this formidable operation was performed at La Charité, by M. Roux. The patient died in twenty-four hours after the operation." (See *Practical Proprietary of the Parisian Hospitals*, by P. S. Kæmper, p. 17.) Langerbeck's excision of the whole uterus, by cutting through nearly the whole of the ligament, I do not deem it necessary to detail, as it is a proceeding which I would never recommend to be imitated. The poor woman experienced the same fate as the patient of M. Roux.

Even with regard to the excision of the cervix uteri, it is perfectly manifest to me that many of the cases in which it was performed were not truly cancerous. Doubts may be entertained, I think, whether the enormous tumour reported in the very first instance of such operation by Hunter, was really a cancerous affection. Several of the cases operated upon in Paris, were decidedly not of this character. On this point I fully agree with Dr. Brown, an eye-witness, who remarks: "While I admit the facility with which such a measure may be accomplished, I must be permitted to doubt its necessity in some of the cases related. The second and third were, in my opinion, such affections as would have yielded to common local and constitutional measures, and would, I have to doubt, have been so treated by British surgeons, and perhaps by a few of our French brethren." (See Brown, in *Edin. Journ. of Med. Science*, vol. vi. p. 29; and M.

Recond's *Obi. upon Ovar. of the Cervix Uteri*, in *Journ. Robinsonianæ*.) M. Velpeau, who regards the excision of the cervix uteri as an operation so completely established as to render unnecessary any reply to the arguments used against its performance by Wood and Zang, acknowledges that the difficult point is to lay down precisely the indication for it. "The elevation from simple hypertrophy of the neck, being rather an infirmity than a disease, never requires it. Extrusions, ulcers, syphilitic growths, not being of an incurable nature, are none of them cases for it. The same may be said with respect to the inflammation and lumps free from pain, whether attended or not by chronic inflammation, so often met with in females between the ages of thirty and forty. It is only, then, in well-marked cancerous disease, that the operation is allowable; but here is the difficulty of the question. In truth, so long as cancers live from absorption, or does not present itself in the upper part of the vagina, in the form of a mass or less located mass, the diagnosis is exceedingly difficult. The intensity, or natural consistency of the cervix, the variations in its size, postures, and density, and form, according to the age and different conditions in which the female may be, demand, in the first instance, great ability, in order to prevent the belief in affections of which not a vestige exists. Then, how can there be any certainty of a lesion so deeply situated in the midst of so condensed a texture, and composed of elements so changeable? This is not all: when the symptoms of cancer is inconstant, its limits must still be ascertained. On this point, details are seldom quite removed, till the disease is far advanced; and scarcely ever can a guarantee be given that the cervix is the only part diseased, and the body of the uterus not yet attacked." However, encouraged by the fact, that the cancer of the uterus sometimes hangs about the neck of the system, M. Velpeau would absolutely renounce the operation. "It is better," says he, "to try it than abandon the woman to a certain death, whenever the disease leaves a hope that the whole of it may be removed." (See *Nouv. Elem. de Méd. Opér.*, t. iii. p. 616.)

In one instance, Dr. Brown, in the attempt to remove the cervix uteri, tried to draw down the latter part: "For this purpose," says he, "Bainson's speculum having been introduced, its blades were dilated and held by an assistant; the hooked forceps were then passed through the tube, and fixed on each side of the cervix. Gentle traction was then exercised (the speculum having been withdrawn) upon the two forceps, which seemed to produce more weakness than is usual, till a considerable portion of the circumference appeared within the blades. It was now found that the 'excrecence' had been torn off from the cervix, and remained attached only by a portion of the lining membrane: this was divided by a blunt bistoury passed cautiously on the finger, and the tumour removed. Attempts were now made to fix the hooks into the lower part of the uterus, in order to remove the diseased surface from which the new growth had originated; but the instruments uniformly separated from the parts being unusually soft. One of the forceps was at length passed into the os uteri, with a view to fix it there, when a discharge of thick pus, to the amount of about one ounce, flowed; and, on passing up the finger, the ante-

tion of the uterus appeared so ineffectual, (throughout of every kind,) that further attempts to excise the cervix were considered inadvisable. The vagina was therefore washed out with cold water, and cold compresses applied; about two ounces of blood were lost. The uterus did not appear much enlarged. The woman recovered, and became free from all her previous ailments. The narrative deduced from this case by Dr. Keeney, and I. W. That it may not be all ways justifiable to excise the cervix uteri, or even to draw it down in that position. 2. That uterine or the uterine cavity may exist as a distinct entity, without any decisive symptom to denote its presence. 3. That very great relief, almost amounting to a cure, may be afforded by the evacuation of such purulent discharges." (*Op. cit. vol. 11, p. 27.*) The original disease appears to Dr. Brown to have been chronic inflammation of the cervix, leading to the formation of pus within the cavity of the uterus, and accidentally complicated by the existence of a small exostosis. The absence of hardness and lancinating pain, he says, defines that it was not cancer. The whole history of this case and its conclusion thus show, and of course the case is another example of which, the excision of the cervix uteri was not necessary.

Instead of the excision of the cervix uteri for cancerous disease, M. Bayle advocated the application of caustic; and his advice was justified upon the fact shown by pathological anatomy, that, in the early stage of malignant ulceration of this part, the texture of the uterus is healthy at the distance of two or three lines from the ulcerated surface. The patient having been placed in the right position, and the speculum introduced, the cancer is to be cleared with doses of caustic, introduced by means of a long pair of forceps. If the surface is irregular, or the seat of fungous granulations, they are to be removed with curved scissors, or a sharp edged kind of scoop, (Duguesne.) In this manner, indeed, such growths may be removed, not only from the cervix, but from the interior of the uterus. After the ulcer has been cleared, a roll of caustic is placed below the speculum, in order to protect the vagina from the action of the caustic. Then the caustic is applied, either the arsenical paste, (Bayle,) or the pure potash, scraped to a point, and fixed in a pinto-crayon; or the acid nitrate of mercury, with which lint is soaked and conveyed with forceps to the ulcer. The application is continued for one minute; then copious injections of tepid water are employed for the removal of the absorbed particles of caustic; the caustic and speculum are withdrawn, and the patient put into a warm bath. In about four or six days, the application is to be repeated; and, if no ill consequences follow, it is to be continued at short intervals, ten more and more lightly each time as the proportion as the cure advances. (*Lancet*; also *Malpighi*, *38th of Med.*, p. 745, ed. 2.)—C.

UTERUS, POLYPUS OF. The fact alluded to by Cooper, that polypus uteri has not the same tendency to return, when partially extirpated, that polypus nasi has; is fact, that partial extirpation, whether by the knife or ligature, is always followed by death of the portion remaining attached to the uterus, in very well

illustrated by a preparation in the Obstetrical Museum of the College of Physicians and Surgeons, New York. The tumor was removed from the uterus of a lady, who had for three years suffered with the symptoms of polypus. The ligature was applied by Dr. Deland, late Professor of Obstetrics in this college. The second day after the operation, on attempting to tighten the ligature, it broke, and the cancer came away. Seven days after this the tumor was seized with a pair of strong lithotomy forceps, and, after slight resistance, was brought away. On examination, it was discovered that the tumor had not parted at the point where the ligature was applied, but that it had pulled off from the uterine mucous membrane about an inch higher up. The preparation now presents the body of the tumor, the neck distinguished by the application of the ligature, and above, an expansion terminated by a smooth surface, about the size of an acetabulum, where the polypus was attached to the vaginal cervix. This fact suggests the probability, that polypus of the uterus, like those of the bladder, may at first be formed of detached cords, which afterwards becoming organized, unite to the uterine parietes by simple adhesion. This hypothesis will account for the fact of their destruction by ligature upon any part of their structure, and their subsequent separation from the uterine wall, and coming away entire.

Professor Francis, of New York, adheres to an opinion similar to that of Professor Cooper, and is strengthened in this belief, from facts associated with a case of polypus at the fundus, which having been partially removed, pregnancy occurred subsequently, and to an issue followed. There is no evidence of polypus at present existing, and the uterine functions are sustained with their wonted regularity.

Anglican experience, according to Dr. Francis, of New York, justifies the use of iodine, both internally and externally, in a large class of uterine affections. No remedy, according to Dr. Francis, exists a more general and salutary influence on the great vices of the female economy. In cases of sterility or barrenness, its impotence has been demonstrated in many instances; irregularities, arising from difficult menstruation, and the non-appearance of the monthly hæmen, have been overcome; in short, the hydroiodate of potash, among other forms of iodine, is ever to be kept in mind in various recent cases of this nature. See also Francis's third edition of *Dequain's Midwifery*.—Bast.

OVULA. The excision of the ovula, as a part of it, when elongated, is often necessary in cases of obstruc-tion. It can often be accomplished with the scissors, but Dr. Physick conducted an instrument for introducing the ovula, on the same principle as that which he subsequently applied for excising the testis. The removal of the ovula has often been performed for spawning, when the ingredient is admitted to a narrowness of the passage, from the glans to the mouth, and in such cases the testis are often excised. Dr. Physick's paper on the subject is in the *Amer. Journal*, for 1827. Everard, both of the ovula and testis, has long been known to be useful in certain cases of sterility. Mr. Brax, a surgeon, of Manchester, has divided also the frenum epiglottidis.—Raman.]

V.

[VAGINA. Dr. Mayo, of Cincinnati, has three successful, by dissection, in separating the walls of the vagina, which had adhered throughout their entire length. In each case, the admission was of four years standing.—*Watts.*]

VARICOCELE. In this disease may be felt, in the course of the spermatic cord, an irregular swelling, consisting of several enlarged vessels, which swelling has a pyramidal shape, with the broad part towards the testicle, and the narrow part towards the abdominal ring. When the patient lies on his back, the tumour diminishes, or disappears altogether, because this position promotes the return of the venous blood; but when the patient stands up it reappears, because the column of blood in the spermatic vein has then to meet against its gravity. Moderate pressure with the hand will make the tumour disappear, not all at once, but gradually; and, when the pressure is taken away, the swelling reappears, not suddenly, but in a slow and gradual manner.

The spermatic veins, (M. Velpéux observes,) which are tortuous, anastomosing, very large, and to the number of two, three, four, or even more, are readily distinguishable from the epididymis, and usually placed in front and at the sides of the other vessels. Long, soft, distensible of valves, continually dragged by the weight of the testicle, enveloped in loose cellular tissue, exposed to compression in the normal canal in consequence of the double bend which they make, and being also equally pressed upon in the sheath in front of the tunicle, by the end of the ileum, or its caecum, on the right, and by the sigmoid flexure of the colon on the left, it is not surprising that the spermatic veins should frequently be the seat of varicose dilatation, and that a varicocele should become sometimes very large. The kind of loosely chain, which they then form, gradually enlarges as they approach the testicle, because their branches increase in number in proportion as they come nearer to the lower end of the cord. This fact proves, that in order to cure them by section or ligature, it is essentially practised, (*Prof. Agric. Sprengel, t. vi.*) and in modern times successfully by Dieffenbach, they should be exposed as high as possible. (*See Alf. Wilson, Ann. Chir., p. 190, L. E. Rev. Paris, 1838.*)

Mr. Mayo joins J. L. Petit, Cullen, and Richerand, holding that it is more frequent on the left side than the right, "owing to the peculiarities of the sigmoid flexure of the colon over the left spermatic vein. But the same reason (he adds) it is often benefited by paring" (*Quæst. of Human Pathology, p. 382.*) M. Blandin also specifies, as one cause of varicocele, the pressure of the large intestine on the spermatic vein. (*See Dict. de Méd. & de Chir. Pratic., vol. xv. p. 212.*) The indurateness of the spermatic veins having no effect, a large corpus, and not testicle coats, and the blood in them having no effect against its own weight in the erect posture of the body, must all give a tendency to a varicose affluence of its lower branches. It is sometimes alleged, that even in persons who are not habitually colicky, the left spermatic veins are naturally more tortuous and

capacious than the right. Cruveilhier also takes into the account the generally larger size and lower situation of the left testis, as possibly concurring. (*Monat., vol. iii., p. 564.*) Persons who ride much are very liable in the disease, and so are residents in warm climates.

In general, nothing more is required than the suspensory bandage, cold applications, poultices, and sometimes leeches, to remove any temporary inflammation or pain resulting from varicocele; and then the disease remains stationary, the patient merely wearing the suspensory bandage, without which the scrotum usually soon returns. Patients with varicocele should also have attention to cold bathing, and avoid coitiveness, which precautions, if not adequate to effect a radical cure, will generally keep the disease from making progress and becoming troublesome.

Couch and other writers relate cases, in which the pain was so intolerable and insupportable, that castration was the only means of relief. Putting castration out of the question, let us briefly inquire what expedients have been tried when the disease is productive of unusually severe pain, and resists ordinary treatment. Some practitioners, on the authority of Cullen, have cut down upon the varicose veins and put tilularies round them. In one instance, Sir Almonst Howard, like Paul Camero, at Treviso, performed such an operation in St. George's Hospital. "In this case, venous inflammation took place, attended with so much constitutional disturbance, that the patient nearly died." (*See Annals of Medicine, in Lond. Med. Rev., vol. xiii. p. 519.*) At the present day, this use of the ligature is abandoned; for if not followed by a gangrene or fatal attack of phlebitis, it would certainly be so by atrophy of the testis.

J. L. Petit, in several instances on many the districts of varicose spermatic veins, as is stated, with such effect, that, in one instance, where the varicocele had been so large as a child's head, previously to the operation, the testis of the testicle, which had been in a weakened state, was strengthened by this procedure. More generally, however, atrophy, or sometimes even suppuration of the testis, might be a consequence of the ligature or section of the veins. It appears that the latter was what happened to the patient operated upon by Dieffenbach, and by whom simultaneous double surgery was ascertained not to be wrong. (*See Monat., Opht., vol. iii., p. 45.*)

In the hope of avoiding both pain and atrophy of the testis, M. Duvergne recommended passing under the vein, through the inguinal ring, a pin, over which a thread was twisted so as to make pressure. With the same view M. Brocq proposed diminishing the pain by pushing it up together with the skin, by means of a pair of counteracting forceps. Another practice is that of the Ficker, which consists in passing a seton, of three or four threads, through the handle of varicose veins. In a case of varicocele of such severity as to require an operation, Mr. Mayo would be disposed to recommend the application of potassa fusa to the places of rings, having first exposed them by dividing the skin. (*Quæst. of Human Pathology, p. 382.*)

The practice advised by Broussais or Frickel has the recommendation of simplicity and tidiness. But I believe the necessity for any operation is very rare. In one case, where the pain was excessive, and supposed to arise from pressure of the vein on some nervous filament, Sir Benjamin Brodie divided the skin, and then cut through the vein with a pair of scissors.

"A little bleeding took place, but none of any consequence; pressure for a few minutes stopped it. The wound healed in an uneventful followed the operation, and the patient was entirely relieved of the pain he suffered previously." (See *Lond. Med. Gaz.*, vol. xli. p. 572.) In another case of high varicocele, in a boy, the same gentleman applied a flaster over the tumour, and kept it open, and the varicocele and the pain were considerably lessened by it.

"Broussais's plan of grasping the veins, whether at the end or of the extremities, by forceps constructed for the purpose, has frequently answered, and has not often been followed by the severe and dangerous symptoms of phlebitis. The parts included in the forceps, not excepting even the vein itself, having sloughed, the ulcer healed. Mr. Sisson has constructed forceps for the same purpose, with blades so bent, that he keeps the sides of the vein in contact for the extent of nearly an inch. It is said to be not absolutely necessary that the vein should be included between the blades of the instrument, nor that adhesive inflammation should arise. It is sufficient that the vein be compressed, so as to stop the course of the blood when a clot forms, which is subsequently absorbed, leading to obliteration of the cavity of the vessel."—(*J. C. Crooke*.)

The passing of needles through the various vein, after the ingenious manner first practised by Mr. Benjamin Phillips, for the obliteration of arteries, has been recently tried by Lallemand, Daval, and Velpeau. The last five also passed needles through the vein, and twisted a ligature spirally, or in the direction of the fig. 8, under the projecting ends of each needle, so as to compress the vein. Mr. Crooke has likewise tried this plan, and, although there was suppuration in the cellular substance, neither general fever nor phlebitis arose, the patient being quickly cured of a troublesome tinea, and the dilated vein returned, or obliterated. In University College Hospital, Mr. Liston follows the same practice, with the improvement of withdrawing the pins at the end of about forty-eight hours, whereby the sloughing and absorption, produced by the pins being left to make their way out, as exemplified in the method adopted by the above mentioned practitioners, are completely avoided. I consider this practice, as modified by Mr. Liston, to be, upon the whole, one of the best and safest plans for the obliteration of the channel of a vein.

Mr. Wernsdorf, his lately mentioned German cases in which painful varicoceles were removed by means of a ring, about an inch in diameter, made of soft silver wire, of a suitable thickness, yielded, and covered with wash leather. "Through this (says he) I drew the lower part of the scrotum, while the patient was in the recumbent position, and the veins comparatively empty. I then pressed the sides of the instrument together with sufficient force to prevent the scrotum escaping. The use of this instrument, every morning before the patient rose from his bed, enabled him to walk nineteen

miles on the third day after its application; and although he has for six years been in possession of the description, he has never experienced the least inconvenience." (*Med. Gaz.*, April, 1838. *J. A. Murray, de Circulo Uteri*, 1834. *Pott on Hydrocele, &c.* Richter in *Ann. Chir.* *Grat. No. 19.* and in *Obs. Chir. Soc. B.* p. 22. *Goose, Chir. Books, Musc. Lat. de Cuvier*, Baur, 1786.)—C.]

[Dr. J. C. Warren, of Boston, has been extensively successful in the treatment of this disease. In one case, he employed only a temporary ligature; in two cases, he used pins with the ligature; and in numerous cases, he performed excision; and in all these cases cured the disease.

Dr. J. Mason Warren, of Boston, has operated on fifteen cases with the same success. In three, he excised the veins; in five, he used the ligature; in six, he employed the pins; and in two cases, he adopted Sir Ashley Cooper's plan, by excision from the scrotum.

Dr. Geo. W. Norris, of Philadelphia, reports in the *Amer. Journal and Med. Examiner*, for 1838, cases of cancer and varicose veins, upon which he operated with success, by the method of Bland.

Dr. N. H. Smith has invented a new method of securing a portion of the pinning on Sir A. Cooper's plan of treating thrombosis, and which has very great advantages. He employs two flat semicircular blocks of wood, perforated near their round edges, for the passage of the needles, and for applying the ligatures; figures are left upon the edges of the blocks, so that the sutures may be all tied immediately after the excision, and before removing the blocks. His success is the best evidence of the superiority of his mode of operating.

Dr. F. H. Hamilton, of Rochester, has a paper in the *Boston Med. and Surg. Jour.* for October, 1841, in which he criticises all the various modes of operating for the radical cure of varicocele, and reports two cases, in which he divided the cord, ligated the vessels, and removed the testis on the affected side. In both cases, vitality remained as perfect as ever. Dr. H. thinks that castration is, in many cases, preferable to any other mode of operating for varicocele, and that the diseased testis being removed, there is less danger of the loss of vitality by the destruction of the other testis, than if the gland of the other side remain and perish, as it does under the other modes of cure.—(*Ibid.*.)

[EVANS, DISEASES OF. It was not till the latter part of the last century that any notice was taken of the veins like cancer, or various enlargements of them, requiring particular attention. At that period, indeed, Hunter noticed the fact of the veins in horses being sometimes found to be enlarged, thickened, and filled with pus. (*Trans. of a Soc. for the Improvement of Med. Knowledge*, 1793.) The observations which he also made on the local and constitutional effects of the inflammation of the veins in the human subject, drew considerably attention to the disease, on which a great deal of interesting pathological and practical information was acquired.

In some points, the diseases of veins resemble those of arteries; but in others, they differ from them. Thus, as Arterial aneurysms, in the veins an aneurysmal state is observed, corresponding, strictly speaking, to aneurysm; because their coats all yield equally to any pressure to which they may be subjected; whereas, in the arteries,

It is only the external coat which is capable of yielding in this way. (*Précis d'Anat. Pathol.*, t. II. p. 382.) The veins are rarely the seat of calcareous concretions, which are very common in the arteries; organized coagulated blood is more frequently met with in the former than the latter; and the same remark is made by M. Andral with respect to pus. "When pus is met with in arteries," says he, "it must be the majority of cases be looked upon as having had its source in these vessels; but when met with in veins, it may either have been produced in them, or have been introduced by absorption." (*P.* 392.)

When the inflammation of veins is not very extensive, its symptoms are the same as those of local inflammation in general; but when the inflammation extends into the principal venous trunks, and this is poured into the vessel, it is accompanied with a high degree of constitutional irritation, and such symptoms which bear a striking resemblance to those of typhus fever.—(*On the Inflammation of Arteries and Veins*, p. 311, 312.)

Inflammation frequently produces a thickening of the coats of the veins, as well as adhesion at their sides and obliteration of their cavities. Indeed, in some instances, these vessels have been found to resemble arteries in the thickness of their coats, and in retaining a circular form when cut across. (*Holgren, Op. cit.*, p. 513.)

Ulceration sometimes extends to the coats of veins, and by exposing their cavities gives rise to hemorrhage. In certain examples, it commences in the membranous lining, and destroys the other coats. In general, however, the adhesive inflammation permeates the ulcerative, and by obliterating the cavities of these vessels, prevents the occurrence of hemorrhage. When suppuration takes place in the vicinity of veins, their cavities, like those of arteries under similar circumstances, are filled with extensive plugs of coagulum, which prevent hemorrhage upon the separation of the mortified part.

Veins are sometimes ruptured without any previous morbid alteration in their structure, and the accident may be induced by muscular exertion, external violence, the sudden effects of the cold bath, &c.

Although a deposition of calcareous matter almost invariably takes place in the arteries of persons advanced in life, it is an extremely rare occurrence in the coats of veins.

Loose canals have been found in the cavities of veins; and tumors sometimes grow from their lining. In a case of scirrhus pylorus, Mr. Hodgson found a tumour, larger than a hazel-nut, growing from the lining of the splenic vein, and resembling, in its appearance and consistency, the disease which selected the pylorus. (*P.* 393.)

The veins, like the arterial system, appears to be capable of carrying on a collateral circulation, when any part of it is impervious. Even after the obliteration of the vena cava inferior, the blood has been known to be conveyed with facility to the heart through the smaller veins and vena argea. In the case recorded by Dr. Baillie, (*Treatise on the Inflammation of the Veins and Arteries*, vol. i. p. 127,) the vena cava was obliterated at the pericardium; the vena cava superior opened into it, so that not only the blood from the lower extremities, but also that from the liver, must have passed through collateral channels to the heart.

To inflammation of veins, M. Broussais first applied the very appropriate name of phlebitis, which, as M. Cruveilhier remarks, belongs both to medicine and surgery; there being a *venous phlebitis* and a *sympathetic phlebitis*, independent of any previous local injury. In France, he believes he has ascertained, that the greater number of individuals who die in consequence of venous and surgical operations, perish from phlebitis. (See *Trat. de Med. et de Chir. Prat.*, t. XII. p. 638, and *Anat. Pathol.*) In this metropolis, we find that a certain proportion of persons so circumstanced are thus destroyed, but not to the same extent as seems from M. Cruveilhier's account to happen at Paris.

Another division of phlebitis, adopted by this eminent pathologist, is, first—*acute phlebitis of free veins*; secondly, *phlebitis of veins contained in the substance of organs*; and, thirdly, *capillary phlebitis*. It is also distinguished into *cellular phlebitis*, where merely dense, or coagulable lymph, is effused within the vessel; and *suppurative phlebitis*, where pus is formed; the latter difference being decidedly the most important as relation to the severity and danger of the affection.

The first effect of every phlebitis is the coagulation of the blood, which becomes adhesive to the inner coat of the vessel. Each coagulum is absorbed, both in a systematic and in sympathetic phlebitis; and it constantly takes place in the experiments which Professor Cruveilhier made in living animals, whether by the introduction of a slender stick, or of a stimulating injection into the veins. In consequence of the interruption of the venous circulation in the inflamed vessel, the blood in it becomes stagnant, and, unless the collateral veins suffice for the circulation, there is an effusion of serum in the neighbouring parts. The painful oedema, the *phlegmasia alba dolens*, of paronychia, &c., as well as that which follows phlebotomy, or under any other circumstances, may be considered, says M. Cruveilhier, as a characteristic mark of phlebitis, and it is generally proportionate to the obstruction of the venous circulation of which it is the consequence. But, besides oedema, external phlebitis is accompanied with a hard, painful, and circumscribed cord, which runs precisely in the course of the vein. Inflammation of the lymphatics is readily known from phlebitis, by the minute size of the painful cord; its more superficial situation; the sinuous small knots, which are perceptible in it; the rose-coloured redness of the skin in the course of such cord; and other particular circumstances depending upon inflammation of the lymphatic vessels. But, with respect to the diagnostic differences between inflammation of deep-seated veins, and that of deep-seated lymphatics, M. Cruveilhier is of opinion, that they have not yet been determined.

The greater number of examples of phlebitis, says when abandoned to themselves, do not exceed the degree of inflammation which has, on its results, the coagulation of the blood with adhesion of the clot to the vessel, and which M. Cruveilhier terms *adhesive phlebitis*. Now (says he) this adhesive phlebitis is as frequent a situation of continuity in the veins: there is an adhesion without adhesive phlebitis in the uræmic veins, corresponding to the phlegmasia; so amputation, he would, on ligature of the arterial cord, without adhesive phlebitis in the divided vein. (*Cruveilhier, Op. cit.* cit.)

The adhesive form of phlebitis cannot be re-

garded as a very serious disease. The effects which follow the coagulation of the blood, do not extend beyond the affected vein. The blood gradually becomes deprived, first, of the serum which it may contain, and, secondly, of the colouring matter, the remaining fibrine either becoming organized or absorbed, and, in both cases, the veins being rendered aneurysmal. In other instances, as M. Cruveilhier shews, several facts and experiments tend to prove, that a passage for the blood may be formed through the thrombus, so, that the vessel that has been the seat of phlebitis only, after a time, be restored to its function in the circulation.

The formation of compact adherent clots, constituting adhesive phlebitis, is described by Cruveilhier as productive of no inconvenience; the individual being unconscious of its existence, except when it occupies a certain extent, and causes more or less interrupting of the circulation in the corresponding parts. Thus, (says he,) adhesive phlebitis of the sinuses of the dura mater is mortal, because the venous circulation of the brain is more or less interrupted. Thus, phlebitis of the temporal or external iliac vein occasions a more or less firm adenomatous swelling of the lower extremity, and sometimes even an impossibility of the circulation being carried on by the collateral veins; but (adds M. Cruveilhier) phlebitis is positively curable in this last stage, even in adhesive phlebitis. (See *Dict. de Med. et Chir. Franç.*, art. *Phlébite*.)

In many cases of phlebitis, neglected, or treated unsuccessfully, the formation of an adherent thrombus is only the first stage of the disease; suppuration is the second; and the phlebitis, which was at first adhesive, now becomes suppurative.

It would appear, that certain states of the atmosphere, or of particular localities, in short, all those which promote the occurrence of hospital gangrene and typhus, give a tendency to suppuration in veins; and hence, MM. Ribes, (*Soc. Méd. d'Emulation*, t. viii. 1847,) Bressler, (*Journ. Complém.*, t. ii. and iii. 1849,) and Broussard, (*Revue Méd.*, Juin, 1853,) have regarded the symptoms of typhus as more or less directly connected with phlebitis, or the presence of pus in the veins.

According to the investigations of M. Cruveilhier and other pathologists, a species of cases of the conversion of adhesive phlebitis into the suppurative, is some irritation of parts already in a state of inflammation, as, for instance, that produced either by attempts repeated at short intervals to extract dead bone, or a ball; that resulting from amputation performed in parts, which are the seat of an inflammatory process; or, still more commonly, the plugging up of an inflamed vessel for the stoppage of secondary hemorrhage.

With respect to the local changes attending the suppuration of veins, the first is the deposit of pus; and according to M. Cruveilhier, this happens, not between the vein and the clot, but in the very centre of the latter. At first, it has the appearance of wine lees, and then it becomes white and opaque. "The presence of pus (says he) in the centre of clots of blood, has led to the idea, that these clots were directly organized, and capable of inflammation and suppuration; in the same manner as it is admitted that the pus, or serum, which, in phlebotic effusions, is circumscribed on every side by a recently formed false membrane, is the product of an exhalation from

this membrane itself; but it seems to me more rational to admit, that the coagulum in phlebitis, and the false membrane in phlebitis, serve, in some measure, as filters, through which the products pass, which are secreted by the internal surface of the vein, or by the phlegon. The presence of pus, then, in the centre of a coagulum would appear, according to my view, to be a phenomenon of the capillary system." (Cruveilhier, *Op.* et *voll.*, tit. p. 641.) I quote this statement, because it presents, in a few words, the opinion of a most distinguished pathologist, on a point which is of some importance in relation to the theory of suppuration. (See *Suppuration*.) There are some examples of suppurative phlebitis, where the disease does not extend that first stage, in which the pus occupies the centre of the coagulum, and then the pus is deposited in abscesses, and the removal, or the organization of the coagulum itself may not even, without the presence of pus having been indicated by any symptoms. But, if suppurative phlebitis continues to make progress, the proportion of the circumferential vessels; that of the coagulum; and the vein soon becomes distended with this fluid. The pus is very seldom remarked to occupy uninterruptedly a considerable extent of the vessel. The inflammation, as M. Cruveilhier observes, not having the same degree of intensity at different points of the course of the vein, the result is that adhesive phlebitis, or incipient suppurative phlebitis, are interrupted by completely suppurative ones, and most commonly an adhesive phlebitis is situated at the limits of the suppuration, so as precisely to circumscribe it. All these appearances are excellently depicted in Cruveilhier's great work. (*Ann. Pathol.*, liv. xi. pl. 1.)

In a more advanced stage, the distended vein becomes knotty at the points where the pus accumulates. Such distensions may be carried to the degree, in which one might suppose the case to be an aneurism, not situated within the vein. After a time, indeed, the coats of the vein may give way, and then the pus beginning effused around, an abscess really follows suppurative phlebitis, and bursts externally; in which abscess it is sometimes difficult to recognize the vein, a more or less considerable portion of which is destroyed. To this stage of suppurative phlebitis, M. Cruveilhier refers—1. The fact, recorded by Mr. Teasdale, who found the internal jugular vein perforated, and communicating with a neighbouring abscess. 2. That reported by M. Kalkbrenner, who found the right common iliac vein ruptured by a very large fungiform sort of abscess, the extension of which was lost in a large abscess, situated in the cellular tissue of the pelvis, on the right side of the bladder. Nor could the slightest vestige of the femoral vein be detected, its track being occupied down to the knee by a mass of circumferential purulent matter. 3. M. Cruveilhier himself published an instance of suppuration, perforation, and partial destruction of the femoral, popliteal, posterior tibial, peroneal, and other veins, with communications existing between these vessels and abscesses. (See *Ann. Path. Méd.*, 1836, t. ii. p. 120.) "In this case, (says M. Cruveilhier) I was able to trace all the degrees of phlebitis, from coagulation of the blood to complete destruction of the vessel."

Phlebitis, even in the suppurative forms, produces only local consequences, so long as the pus is circumscribed by the adhesive inflamma-

tion, and the portion of the vein, which is the seat of suppuration, is excluded from the circulation of the blood. We find this condition described by John Hunter. Professor Cruveilhier alludes the following example of it: "A woman, seven or eight days, was affected with phlebitis in one of the superficial veins of the breast; the vessel formed a large indurated painful cord, extending transversely directly below the nipple; a fluctuation was felt at the inner extremity of the cord. There M. Cruveilhier made a puncture, and was surprised to find that the vein was immediately emptied by pressure made in the direction from without inward, and the prominence of the cord converted into a furrow." Suppuration went on for a fortnight, and the pus frequently collected again in the vein, in consequence of the closure of the small opening. The pus was succeeded by a limpid serum fluid, the constant presence of coagulative adhesive inflammation, which was soon manifested. However extensive phlebitis may be, provided the pus collected in the vein does not communicate with the mass of circulating blood, the effects of the disease are entirely local. The pus, like that of other abscesses, may be absorbed; or it may distend and thin the vein, and make its appearance through the ulcerated coats of the vessel, so as to cause an abscess liable to be mistaken for a common one. But, as M. Cruveilhier adds, no sooner is the tube formed by the clot broken, and secretly removed by absorption, and the stream of fluid abroad in, than typical symptoms immediately begin, preceded by violent shiverings, and soon followed by death. Frequently, the patient, who had been left perfectly free from indisposition on the previous evening, is found in the morning in a desperate state; in some cases, very nearly the precise moment of the entrance of the pus into the circulation may be specified. (Cruveilhier, *Dict. de Méd. et de Chir.*, t. xii, p. 513.)

Another fact, particularly explained by the same pathologist, is, that no ordinary mark of inflammation is ever noticed upon the inner surface of the vein in the various stages of phlebitis; that is to say, no injection of capillary vessels can be remarked. The does not colour, noticed by Cruveilhier and other pathologists, resembles a kind of pain, or agglutination. This it would seem, is observable in the adhesive stage, and entirely vanishes when pus takes the place of the coagula. These facts M. Cruveilhier deems of much importance, because the absence of the anatomical phenomena of inflammation upon the internal coat of the vein, and more especially of all injection of the capillaries, has served as the principal argument of writers, who contend that pus found in a vein is not formed there, but in some other part of the system, whence it has been conveyed by means of absorption; but, as he observes, there are some membranes with which cannot be injected, and in the healthy or morbid state: such are serous membranes, the fibrous epineurium, peritoneum, tunica mucosa, the internal coat of a vein, and also the cellular tissue. When there is no phlebotomy, and no pus in the vein, it is by the easiness of the external coat, and the diffusion and fulgurance of the cellular tissue on the outside of it, in which a plastic lymph has been deposited, that one may recognise the traces of venous inflammation.

It has sometimes been supposed that the inflammation of a vein always extends only in one

direction towards the heart, or in the course which the venous blood itself takes; but this is a mistake as anybody may convince himself by reading the interesting particulars of a case of phlebitis following a gunshot wound of the arm, as recorded by Cruveilhier, (*Ann. Pathol.* liv. xi.) and the plate representing the appearance of the veins. There it will be seen, that phlebitis may extend simultaneously, not only in the direction towards the heart, but in the opposite one, by continuity to the smaller veins.

Professor Cruveilhier has given an excellent description of the general phenomena of phlebitis, which are such as are very usually noticed in the absorption of pus; namely, exceedingly bad typhoid symptoms, under which the patient sinks with more or less rapidly. "On opening the body, numerous unorganised collections of purulent matter are found in the lungs, liver, spleen, brain, and muscles; purulent effusions in the synovial and serous membranes; and (what is particularly remarkable) this internal mischief is most frequently unattended with any other local perceptible alterations of the affected organs. For the illustration of this part of the inquiry, M. Cruveilhier adverts to the most common phlebitis, that which is the consequence of wounds and surgical operations. The earliest observers, who endeavoured to detect the cause of death in such cases, did not fail to notice the existence of intestinal abscesses in the perforated viscera, and especially in the liver and lungs. Modern pathologists having become also fully conversant with the frequency and gravity of these lesions, do not hesitate to regard them as an ordinary cause of death from wounds. Now, as the greater number of the subjects of wounds and surgical operations were known to have, been previously in perfect health, the venous mischief in their viscera could not possibly be supposed to have existed prior to their wounds. The question then arises, whence does the typhoid matter come from?"

The doctrine of the absorption and deposition of pus, says M. Cruveilhier, so long disbelieved, as well as all the other hygienic doctrines, has lately been revived, and supported with much talent by M. Velpeau in a series of interesting memoirs, and also by MM. Marjolin and Eugene Legros. These authors admit that (as observed in the deep-seated parts, or on the surface of the body, may be absorbed, circulate with the blood, and be deposited in the substance of this or that organ, without any previous inflammatory process in the seat of such deposits. The facts adduced by these pathologists, M. Cruveilhier acknowledges to be equally unassailable; but it is their interpretation of them which he considers may be mistaken. "MM. Velpeau, Marjolin, and others, have supposed in the veins, at the right angles of the heart, and in the course of flow of the blood, like them, says M. Cruveilhier, I have seen the same things all modern observers have likewise done so. Not less frequently also (*Ann. Pathol.* liv. xii.) I have found pus in the lymphatic vessels. Like them, I have seen effusions of pus in different organs; the lungs, the liver, the brain, the spleen, the muscles, and the serous membranes, without any manifest evidence of inflammation around. The veins, the lymphatic vessels, and the heart, though they contained pus, seemed also in the state of the anatomical characters of inflammation." (*Id.*, *ib.*, p. 617.) M. Cruveilhier then offers various

tensions, which appear to him to be in favour of the formation of pus in the situations where it is met with. He objects to explanations, in which the metaphorical expression, sympathy, is substituted for fact. "If the liver is so often affected in wounds of the head, it is, according to Desault and Bichat, because the liver and gastric organs are so closely connected with the brain by sympathy. The whimsical and opposite modes of accounting for abscesses of the liver after injuries of the head, adopted by Fontana and Bertrandi, are well known. M. Richerand suggested the notion that these abscesses were owing to the simultaneous contusion, or concussion of the liver and the brain; and this view may afford a satisfactory explanation of some hepatic abscesses; but the production of those abscesses, with which are to be arranged infantile, mortons of the tympanic and serous membranes, muscles, and cellular tissue, is too general a fact, and, in the majority of instances, too independent of all contusion and concussion, to permit the adoption of so limited an explanation."

Anatomy is invoked in vain to fill the void that bites these phenomena. The porosity of our textures, which, according to the ancients, allowed fluids to filter from one place to another, as through a sponge; the perviousness and continuity of the cylindrical tissue, in the cavities of which fluids made so ready fluids, and even in many cases of disease, more so; imbibition, endosmosis and exosmosis, substituted of late for the porosity of the ancients; the continuity of the nervous and vascular systems; the sympathetic correspondences; the law of consensus; in a word, the whole science of organization, are all confessedly incapable of accounting for so extraordinary an occurrence. An inflammation, which seemed to have nothing to do with that now under consideration, phlebitis, has filled up the great void, that seemed to separate the suppurating wound from a venereal abscess. A series of numerous experiments which I published in 1826, (*Neur. Hist. Med.*, t. iv.) appear to me to have rigorously established this proposition: Every foreign body introduced in the femoral subject into the venous system, or osseous, when its discharge by the membrane is impossible, vascular diseases, completely resembling those consequent to wounds and surgical operations; and such abscesses are the result of capillary phlebitis in these vessels.

¶ If any irritating fluid, such as ink, for example, is thrown into the femoral vein of a dog, (in the direction from the heart,) which is practicable after a few of the valves have been destroyed with a probe, and the collateral veins do not convey the liquid into the circulation, in which case the injection proves immediately fatal, the limb in 20 hours becomes swollen, and if the animal then dies, or is killed, innumerable bloody extravasations are found in the substance of the muscles, and in the cellular tissue of the limb. The large veins are distended with coagulated and adhesive blood; and the small veins, corresponding to the extravasations, are also full of concrete blood, while those appertaining to the healthy parts are free. If the animal survive the experiment, collections of pus replace those of blood, at the same time that pus is substituted for the coagulated blood in the veins. M. Cruveilhier, instead of using a chemical irritating mass, next employed a mechanical one; he passed a stick into the femoral vein of a dog, from below upwards, into the ascending

vein cava. The dog died on the sixth day. The lower extremity was enormous, the infiltration extending up to the pectoral of the chest. All the veins of the lower extremity were full of pus. When the muscles were divided, small abscesses were seen here and there in them, which proved to be minute veins, swollen with purulent matter, which could easily be pressed out of these vessels. Amongst other effects noticed by Cruveilhier, there was also a collection of pus in the synovial membrane of the knee.

M. Cruveilhier then endeavoured to ascertain what became of the pus of a local phlebitis, when such pus was mixed with the mass of circulating blood; but, since purulent matter cannot be detected when blended with the blood, he was obliged to supply in lieu of it mercury, a liquid, the smallest particles of which, however situated, would admit of being traced. Now, he found, that if mercury be introduced into the venous system, whatever be the way of its entrance, (excepting through the abdominal system,) the mercury is always found again in the lungs. Thus, (says M. Cruveilhier,) if a large quantity of quicksilver be injected into the jugular or femoral vein, the animal will become exceedingly oppressed, and perish, in twelve, eighteen, or twenty-four hours, in a state very analogous to that observed in scurvy, or infectious venereal. The whole of the mercury will be found again in the lungs, which will not be infamed, but clogged with serosity; that may be compressed out of them. But if the quantity of quicksilver is smaller, the animal will survive the experiment a longer time, and then there will be perceived an induration around each globe of the mercury; in a later stage, collections of pus, and, at still more advanced period, a mixture of pus and tubercular matter. Lastly, if the animal survive for two or three months, tubercles are found with a globe of quicksilver in the centre of each of them.

M. Cruveilhier alludes to the contemplation of physiologists the following experiment, which he has varied in a thousand ways, and always with the same result. He destroyed the nodular texture of the testis, and substituted quicksilver for it. The dogs experimented upon lived four or five days, and, on opening them, he found all the quicksilver scattered through the lungs, and each globe decomposed by a degree of inflammation. The quicksilver was lodged in the ramifications of the pulmonary artery, which we know perform in the lungs the office of veins.

The liver being the seat of a particular system of veins, which are destined of valves, and have numerous ramifications in the mesentery, M. Cruveilhier drew out a vesicle of intestine, and injected quicksilver into one of the mesenteric veins. In a dog which survived this operation twenty-four hours, he found the liver studded with red, papillary, and slightly prominent patches, of the colour of wine-lem; and in the free space when cut open of a fold with these patches, presented the same colour to the depth of four or five lines. In the centre of each small red induration was a globe of quicksilver; a certain quantity of which had penetrated into the small veins which run on the coats of the intestine. Opposite these small intestinal veins, the mesentery membrane was of a bluish-red colour, and lined with a finer membrane and closely mucous. The corresponding subperitoneal cellular tissue, and the muscular coat itself, were also of a crimson hue.

In another experiment on a dog, which led an untroubled existence, M. Cruveilhier injected quicksilver into a small vein of the abdomen. In about ten weeks the animal was destroyed. The abdomen was found adherent to the exterior of the abdomen; pus, through its whole extent, a great many abscesses, very firm nodules, scattered or aggregated. The liver was studded with innumerable yellowish nodules, some of which lay near its surface; others in its substance, and each having at its centre one or more globules of quicksilver. Some of them presented two distinct studs; one of a tubercular substance at the circumference, the other of puriform matter in the centre, in the middle of which were the tubercular globules. The preceding facts seem to M. Cruveilhier to prove that all extraneous bodies, introduced into the general circulation, are inevitably conveyed to the lungs, and such as enter the abdominal venous system, as certainly proceed to the liver; these viscera constituting a barrier, which they cannot pass beyond except in certain cases.

The experiments quoted by M. Cruveilhier solve one difficulty, which clinical observation alone could never have solved: how, in the hypothesis concerning phlebitis, is the pus conveyed from the general venous system into the capillary system of the liver? Should not the pus stop in the capillary vessels of the lungs? It seems as if abscesses should only take place in the latter organs; yet experience proves, that abscesses of the liver are very common after wounds and surgical operations, and this, notwithstanding the capillary system of the liver only communicates directly with the venous part and the hepatic veins. But this objection is at once refuted by its proper cause by the demonstration of that viscid liquid, quicksilver, passing completely through the capillary system of the liver, when injected into the branches of the venous part; and, in other cases, passing through the general and pulmonary capillary systems; or, what is still more convincing, pervading several times the different orders of capillary vessels.

Perceiving Cruveilhier, therefore, considers it to be proved, with all the exactness of physical experiments, that pus, introduced into the circulation with the blood, is stopped in different departments of the capillary system; that it everywhere excites capillary phlebitis, or circumscribed inflammations, which advance more or less rapidly to the state of abscesses; that pus, like quicksilver, is most frequently stopped in the lungs, and next in the liver and spleen; and that, like quicksilver, it may pervade the capillary system several times in succession, and occasion circumscribed inflammations in all parts of the body.

The next question which M. Cruveilhier considers, why do not modified rheumatic abscesses take place in cases of system accidents, that of pus, for instance, in those from chronic phlebitis and phlebotomy? Is it necessary that there should be a transmissible phlebotomy in some part of the system to produce a capillary phlebotomy in the viscera? All observers, and especially in particular, he says, have noticed the vast difference in relation to consecutive effects between abscesses of long standing, and the suppuration from recent wounds. To what can this difference be ascribed? Is there absorption of pus in one instance, and not in the other? The following is the explanation immediately derived from the

facts:—Whenever a fluid, capable of being absorbed, is in contact with a suppulating surface, whether such fluid be secreted by the texture of the body, or be extraneous to the system, it is absorbed. The absorption of pus is occasionally taking place. "I will not cite (concludes M. Cruveilhier) the numerous cases, which prove the occasional presence of pus in the lymphatic vessels and glands, because pus, so situated, might be regarded as the product of their inflammation; but I will cite the very common and repeatedly observed disappearance of large abscesses, the opening of which has been destroyed." Yet, the constitution undergoes no disturbance from this cause, and the heterogeneous matter is eliminated by the excretories. It appears to M. Cruveilhier, that there is immense difference between pus which is transmitted into the circulation by absorption, and pus which is directly absorbed into it, without having undergone any modification, or preparation, by the act of absorption, or which is produced immediately within the veins themselves. (See *Ann. Pathol. Physico-Médic. liv. (c.) Anatomie des Vaisseaux de la Dure-Mère, liv. (vi.)* Pathology as well as physiological absorption does not act upon substances from mass, but successively on their different elements, which are thereby modified. Pus, in particular, would appear to be in the first instance deprived of its most fluid part, its solid part is not absorbed till a later period, and frequently as it has acquired a consensual consistency, lin. (vi.) A natural conclusion, directly blended with the blood, alters its mass. (as the ancient would say) embarrasses its course, promotes its coagulation, stops it in the capillary vessels, and, at the same time, gives rise to inflammation at numerous points." (Cruveilhier, *Dict. de Méd. et de Chir. Pratique*, t. xix. p. 657.)

It may be objected that, if the foregoing theory were true, modified abscesses in the viscera might always be preceded by phlebotomy in some part or another; yet, frequently, they are met with, and no traumatic suppuration can anywhere be detected. It is in no purpose that all the veins are inspected, and only those which upon a wound, an ulcers, abscess, from it; nowhere can any marks of phlebotomy be traced. Now, on this fact, which excited Mr. Arnet's notice, M. Cruveilhier argues that, unless the state of the medullary canal, or spongy texture of the bones, be examined in such cases, the inference is of no value, because incomplete. M. Duret seems to have been the first pathologist who gave a correct explanation of the cause of abscesses of the liver from wounds of the head, viz. the inflammation of the deep veins, not merely of those which ramify in the brain and its meninges, but also of those which penetrate the bones of the cranium—the veins of the diploe. Pus formed in the diploe, or the meningeal veins, may reach the liver as well as the lungs, and, indeed, every part of the venous capillary system; for the liver is not exclusively affected by vessels of the brain, and, as M. Cruveilhier remarks, if many abscesses have only spreaded the liver, it is because they were mostly supplied with the infection of that vessel. "What M. Duret proposed as a conjecture, has been completely established. In several cases of wounds of the head, the veins of the diploe have been found purulent, and this state coinciding with abscesses of the liver and lungs,

Several interesting specimens of this were presented to the Anatomical Society; and, at the present time, it may be announced (says M. Cruveilhier) as a demonstrated truth, that, in cases of wounds of the head, the vascular diseases, whether of the liver, the lungs, or spleen, &c., are the consequence of phlebitis, and more especially of phlebitis of the juglar; but the observation, that inflammation of the veins of bones, as a cause of vascular diseases, applies, not only to the veins of the spine, but to all the veins of bones; and I lay it down as a general proposition, that phlebitis of bones is *being the most frequent cause of vascular diseases, after suppuration and surgical operations impeding the blood.*" (*Op. cit.* vol. tit., p. 600.)

Treatment of phlebitis comprehends—1. Phlebitis from extension, 2. From the division, extension, or ligation of veins in the treatment of varicose veins, which Cruveilhier is surprised are not the subject of universal attention, considering the fatal consequences frequently occasioned by them. 3. Phlebitis from wounds of the head, gunshot wounds, compound fractures, various surgical operations, lithotomy, the extraction of encephaloid polypi, the excision of hemorrhoids, the prolonged continuance of a catheter in the bladder, &c. Phlebitis has been known to follow incisions for the extraction of bills, the removal of fatty tumours, a meliorism of the head, and even a sacro contusion of the leg. (Cruveilhier.) The last case of phlebitis which I met with, arose from a severe contusion of the elbow, where abscesses formed, communicating with the vein, attended with severe constitutional disturbance, and soon followed by abscesses in both legs, and gas in the synovial membranes of the ankle joints. No suppuration could be traced in the upper leg; but the nodular texture of the bones of the arm was not examined. Phlebitis may indeed come on in the suppurative stages of many diseases. I have known it arise as a consequence of an enormous carcinoma, and lead to the formation of numerous abscesses, several of which occurred in different synovial cavities.

Ulcer of phlebitis is known to be one of the worst forms of pyæmic fever. Next to traumatic phlebitis, see 66. the most frequent cause is phlebitis of the lower extremities, consequent to ulcers and syphilitic phlebitis. This takes at it, however, may take place under two distinct conditions: 1. After paronychia, 2. In cases of cancer of the wound. But, for information on these topics, I must refer to the writings of Dr. D. Davis, Dr. Robert Lee, Professor Cruveilhier, (And. Pathol., liv. xxiv.) and others.

With regard to the treatment of phlebitis, this must vary according as the affection happens to be in the adhesive or the suppurative stage. Or rather, I might say with Professor Cruveilhier, the only period when any means are likely to avail, is that very early one of the coagulation of the blood within the vessel; for when suppuration has taken place, and gas has actually entered the circulation, medicine is generally inefficient. Just as an external phlebitis is fully seen to be checked by bleeding, cold applications, the free administration of calomel, and the application of numerous leeches in the course of the inflamed vein, so may internal phlebitis, whatever its situation, be stopped by early recourse to cupping bleeding, and to the free use of leeches and mercury. I believe all the best practical writers on disease phlebitis

give their testimony in favour of rigorous and phlebotomic treatment, adopted in the earliest stage of the case. Dr. Robert Lee is an advocate for it, and Professor Cruveilhier, in his practice at the *Hôpital de la Pitié*, believes, that he has often subdued morbid phlebitis by means of general and local bleeding; resorted to early, and practised with freedom; but, as he observes, no sooner is the first stage over, and the constitutional derangement begins, than bleeding and leeches have no beneficial effect. Doubtless, he remarks, this may take away, with the blood, a portion of the material cause of the disease, but such cause continues to be incessantly reproduced, and the patient, together with his blood, is deprived of the power of reaction. Under these circumstances, bark, sulphate of quinine, carbonate of ammonia, ether, wine, bread, and opium, or the preparations of mercury may be tried, with or without two or three grains of calomel every night, and with repeated leeches and warm applications. However, it is attested by all who have seen much of syphilitic phlebitis, attended with the effects resulting from the direct influence of pus into the circulation, that no treatment, hitherto suggested, appears to possess any great power over this form of the disease.—[C.]

[Signature of the *Internat. Jugular Syph.*—The following operation is original with Professor Stevens, and has not hitherto been published.]

"The question of the possibility of tying the internal jugular vein in operations for the extirpation of tumours in the neck is one to which the attention of surgeons must have often been directed with great anxiety. The records of our art do not furnish, to my knowledge, any case in which this operation has been attempted. That which I am about to relate establishes the important fact that it may be tried with safety."

"A man of middle age came under my care in the New York Hospital during the last winter, (1820,) with an extensive flattened tumour under the sterno-mastoid muscle, formed at the clavis of lymphatic glands, which encompassed the great vessels on the left side of the neck, in a state of great enlargement. It had been the subject of a previous unsuccessful operation, and was then thoroughly obstructing the passage of deglutition and respiration. In the course of my operation for the removal of this tumour, after it had been detached, except at its base and posterior edge, I drew the tumour externally and backwards, and divided a vein of considerable size, passing horizontally outwards, near its junction with the internal jugular. Half an ounce of venous blood escaped, and in an instant afterwards a pulsing sound was heard, like that occasioned by allowing into a syringe the last portions of water from a basin. It was a moment of intense anxiety, for the state of Digestion's patient was fresh in my recollection. I immediately placed my finger on the aperture in the vessel, seized the pulse with the other hand, and watched the patient's countenance. All seemed well, and the patient's reply to my interrogatory confirmed these favourable indications. After a moment's deliberation, I determined to pass a ligature around the internal jugular, below and above the junction of the wounded branch. It was accordingly separated from the par vagum and carried with the blunt point of an eyed probe, armed with a double ligature; one of which was secured below and the other above the wounded vessel. The operation, of which

effile remained to be done, was then completed. The man suffered from cough and difficulty of respiration between the fourth and seventh days after the operation, for which he was twice bled and took saline purgatives. The lephoria came away on the fourth day, and the case went on without any peculiarities.

"If the par-caverna can be divided on one side without endangering life, a question, I believe, not yet settled by positive experiment, the proposition will be established, that many aneurisms of the safe of the neck (the removal of which has now deemed impracticable) may be successfully obliterated."

The internal jugular vein has been twice tied successfully by Dr J. C. Warren, of Boston.

Professor Hamilton, of Geneva College, who was unfortunate enough to cut the internal jugular vein, in an operation upon the neck, thrust a sponge into the wound, and allowed it to remain until suppuration resolved it. The fibrinous discharge was discharged, and the patient recovered.

In the *Ann. Jour.*, for 1838, Professor Sewall, of Washington, publishes a letter from a medical friend in Paris, narrating a case of death, in the third day, from the entrance of a wire into the veins, in the operation of aspiration at the axillary region, performed by the celebrated Reiss. This letter corroborates the opinions of Magendie on the subject, together with experiments performed on living animals, in confirmation of his views. To this level, but valuable article, I have only space to refer the reader.—*Edin.*

[VEINS, VARICOSE.] Modern pathologists make a distinction between veins affected with simple hyperæmia, and veins in the varicose state. "Hyperæmia of veins (says Cruveilhier) is observed in all cases, where a great morbid or morbid influence action takes place in an organ; as exemplified in the uterine veins during pregnancy, and in cases of considerable hæmorrhæ or morbid outpour, or other growths in the substance of that vessel." Another cause of hyperæmia is some impediment to the course of the blood in the veins, &c. Whatever may be the cause, venous hyperæmia is characterized not only by dilatation of the veins, but by an increase of their length, so that these veins are tortuous, become a first tortuous, and afterwards uniformly twisted on themselves, attaining at last four or five times their natural length, and not recoverable, &c. When the dilatation occurs uniformly at every point of the circumference of the vessel, the blood circulates freely; but if so mixed; but, if one point of the circumference undergoes a change of structure, it yields, and then the blood is detained in it, and a partial stasis of that point is formed. In these cases, congestion, adheres to its interior, loses its red colour, and in the centre of the pile, stasis, varicose congestions are produced. Sometimes the cause of the venous congestion, inflammation, heat, and give rise to hæmorrhages, it says, scaly, dry, and which may prove fatal. There is then, but great difference between dilatation and varix; that, in one, there is integrity of the circumference, in the other, an alteration of them; in one, the vein finds all its contents in relation to the circulation; while, in the other, there is a stagnation of the blood and disease." (*Cruveilhier, Anat. Pathol.*, liv. xvi.) Certain facts, however, noticed in this article, prove that the kind of dis-

tension specified by Cruveilhier is not always pulsatile, inasmuch as the blood is not usually stagnant in varicose veins, and varicose aneurisms are only occasionally met with in them. M. Andral identifies not less than six varieties of veins:

1. Simple dilatation of veins without any other change, such dilatation affecting either their whole length, or consisting of intervals. 2. Dilatation, either uniform, or at intervals, with a dilated state of the vein at the dilated points. 3. Uniform dilatation, with thickening of the venous coats. 4. Dilatations at intervals, with thickening of the dilated points. In these veins had, at the same time that the vein increases in diameter, it increases also in length, and becomes bent and tortuous. 5. Dilatation, with the addition of septa within the vein, whereby the cavity is divided into little cells, in which the blood lodges and stagnates. 6. A singular disposition, combined with perforations in the coats of the vein, which communicates with the surrounding cellular tissue in a more or less diseased state, by numerous small apertures. "In dissecting a great number of true hæmorrhoidal swellings," (says M. Andral,) "never will any thing else be detected, but one of the other of these six varieties of phlebectasia, (varicosity) but this is not merely the case with veins, about the verge of the anus. I once met with the disposition, constituting the sixth variety, in the external jugular vein." (*See Andral, Précis D'Anat. Pathol.*, t. ii. p. 400.)

Professor Cruveilhier has recorded the particulars of a man in whom there was an extensive dilatation of the inferior vena cava, which freely communicated with the venæ portæ, through the intervention of the umbilical vein, the size of which was equal to what it usually presents in the fetus. (*See Anat. Pathol.*, liv. xvi. pl. 6.) The disease rarely occurs before the adult period of life, and its progress is extremely slow. It is very frequently remarked in pregnant women, who have passed a certain age; but it is particularly useful for it to happen in young women, even during a season of repeated pregnancies. Surgeons have not hitherto made out any very precise information respecting the kinds of constitution which promote the occurrence of a varicose enlargement of the veins. Nor has it been well proved that the disease often proceeds from swellings of the abdominal viscera, or any other species of tumour capable of mechanically obstructing the venous circulation. One or more veins of the same kind are at first most commonly affected with a slight degree of dilatation, without pain or any sensation of uneasiness. This beginning change gradually advances with great slowness, except in cases where it accompanies pregnancy, in which it, sometimes, runs its course with the lower extremities, as early as the first months, are frequently accompanied with largely dilated veins, or even with tumours formed by an aneurismal or cancerous. The veins gradually become more and more distended, lengthened, coiled up, and tortuous. The patient then begins to complain of a sense of heaviness, numbness, and sometimes of very acute swelling pain through the whole of the affected limb. In a more advanced age, in proportion as the venous disease, and especially when the dilated veins actually form tumours, the limb swells and becomes more or less edematous, according to the extent of the disease, and the time which it has existed. Delin-

thinks, however, that the edema in this case is not such as to justify the conclusion, that the increased size of the veins, and the way in which they distend the integuments, produce a mechanical interruption of the function of the absorbent system. For, says he, numerous varices are sometimes, both on and often met with, which are not attended with any swelling of the cellular substance; and cases are still more frequently seen in which there is a considerable degree of edema, while the varices are scarcely remarkable. When the latter have prevailed a long while, and made much progress, the coats of the affected veins are not subsequently thickened, swollen, and ulcerated, forming a sort of ball canal or solid tube. As Mr. Hodgson remarks, "the blood occasionally deposits strings of coagulum in varicose veins; when this is the case, the vessel is incapable of being emptied by pressure, and is firm to the touch. The coagulum does not in general fill the vessel, but by diminishing its calibre, it retards the flow of blood, and causes the dilatation to increase in the inferior portion of the vein, and in the branches which open into it." (*Cy. Les. of Arteries and Veins*, p. 541.) This gentleman has seen four cases, in which the coagulum accumulated to such an extent, that the sample of the diluted vessels were obliterated, and a spontaneous cure was the consequence. The excessive distention of the coats of a superficial vein produces an inflammatory irritation, at first in the adjoining cellular membrane, and afterwards in the integuments. These textures become first detached together by the adhesive inflammation; and if the distention continue to operate, they may at length ulcerate, and burst, and hemorrhage be the consequence. In such cases, the effusion of blood is sometimes considerable; but the syncope following it, or a moderate compression, generally suffices for its stoppage.

M. Veljeau cites one case, in which the bleeding from a varix of the leg proved fatal; and I have heard of other similar occurrences. In varix of the extremities, accompanied by chronic ulceration of the integuments, as Dr. Caruswell observes, extensive hemorrhage may be the result of perforation of a vein, not larger than a common quill. "I had (says he) an opportunity of examining the vein in an example of this kind, the morbid condition of which, and of the surrounding cellular tissue, afforded a satisfactory explanation of the fatal extent of the hemorrhage. The walls of the vein were much thicker than those of its artery of the same size, and were so firmly united with indurated cellular tissue, that a considerable degree of pressure was required to approximate their internal surface. The consequence of this condition of the vein was, that its capacity would undergo no diminution during the hemorrhage, the blood continuing to escape, as through an inextensible tube, by the opening which had been effected by ulceration. This patient, who was about 80 years of age, expired in the space of little more than ten minutes." (*See Caruswell's Observations of the Elementary Forms of Disease; Paris, on Hemorrhage.*)

By tying the principal venous trunk above the point to which the varicose branches proceed, it was believed that the flow of blood through them might be so retarded and impeded, that they would afterwards become filled with coagulated blood, and then gradually subside. The operation of tying the venous trunk with two ligatures,

and cutting through the vessel in the interval, has been accurately described by some of the old writers.

After the account of the perils of suppurative phlebotomy, as already given in this article, it is unnecessary for me to offer any further comment on the unjustifiable nature of this operation. In England it is now universally abandoned.

Mr. Ferrall has published an interesting paper, in which he notices the occasional suppuration of the wound after this operation. Such an event took place in some of Mr. Carmichael's cases, notwithstanding every precaution. Between the years 1824 and 1829, Mr. Ferrall performed the operation four times. In three of these suppuration occurred; the he imputes to a degree of laceration of the cellular tissue in turning the knife, proposed by Sir Benjamin Brodie; which was also sometimes found to be so. On this account, Mr. Ferrall recommends another knife with a straight back, and made as thin as possible for about a quarter of an inch from its point, without forming there a cutting edge. Previous to the operation, Mr. Ferrall surrounds the limb with straps of soap plaster, nearly as high as the situation of the cluster of varicose veins, and a roller is applied in the same space, ready to be continued up the limb, when the division is complete. The object of this is to lessen the flow of blood through the tortuous vessels, and consequently their distention and irritation below the point of incision, when the action is interrupted. Mr. Ferrall deems it advantageous to let the bleeding go on for a little while. After the operation, a compress is laid on the part, and the roller, wetted with an evaporating lotion, continued up the limb. The patient is then put in bed, with his limb on a pillow, and the leg higher than the knee. For additional details I refer to Mr. Ferrall's paper. (*See Dublin Journal of Med. Science*, vol. ii. p. 239-254.)

Even when the vein was divided, and the skin left untouched, Bland saw sometimes phlebitis, and sometimes phlegmonous erysipelas, produced by the operation. (*Mémoires, Ann. de Méd. Opér.*, p. 164, et. 2.)

A few months ago, however, Sir Benjamin Brodie informed me, that he now rarely recovers ulcers the plan, as he believes that much of the relief which he formerly imputed to the operation, is the effect of quietude in the recumbent position observed after its performance.

The actual and potential cautery are ancient means for the cure of varices. Of late years, Mr. Mayo has in a considerable number of cases applied caustic, or caustic paste, over the trunk of the subcutaneous veins of the leg affected with varix. In some few instances, on the healing of the ulcer left by the separation of the eschar, no effect on the vein was observable; but, in most the greater proportion, the vein became firm and hard, and its cavity was obliterated at the part where the issue had been made. "I have little doubt, (says he,) that in the successful cases, the irritation upon the vein has caused local subacute inflammation, as a consequence of which the blood has coagulated in its cavity, and plugged it. The vein is often tender during several days, for the extent of three or four inches above the place at which the caustic is applied. The obliterated part does not exceed more than half an inch to an inch in length. I have never known acute phlebitis supervene in employing this practice. In one case, occurring

In a young woman, an interrupted dromed made a circular excision, two inches in circumference, and deep in proportion, over the superficial vein immediately below the knee; it opened the aneurysm, and within six hours there was violent venous hemorrhage; this, of course, stopped on pressure being applied. During the next few days, there was tenderness of the aneurysm, extending half the length of the thigh, over which leeches were applied once." The case ended well. (*See Mayo's Outlines of Human Pathology*, p. 433.)

Instead of dividing the skin, and tying or cutting through the trunks of varicose veins, or the excision of clusters of them, or the obliteration of them with caustic, another practice has arisen, viz., that of raising up the vein, together with the skin covering it, and then passing under the second a long needle or pin. The vein being elevated by means of the pin, is pressed down upon it, and then firmly constricted with thread twisted round the two projecting portions of the pin in the manner of the twisted suture. The subsequent pin, and the thread over the vein, press and flatten it; stop the flow of blood through it, and produce local inflammation in it, which is at first adhesive, then abscessive, and terminates in the obliteration of the cavity, and the division of the venous coats. In about eight or twelve days the pin is withdrawn, the threads removed, and the slough formed in the seat of the compression, left to separate of itself. The remaining sore soon heals up. This method, which was first tried on animals by M. Davat, has been practised by M. Velpeau on twenty-five patients for varices, and with almost-constant success. (*See Malgaigne, Ann. de Méd. Opér.*, p. 161. *Arch. de Méd. et de Chir. Prat.*, t. xv, p. 545.) It appears never to have been followed by any of the bad consequences too frequently occasioned by the simple ligation of the vein. In the treatment of varicose veins, M. Sauton adopted M. Brocchi's plan for the relief of varicocoele, (see this work,) while Dr. Fricke has, in not less than thirty instances, extended the use of the suture to the cure of varices, as well as varicocoele, and with successful results. M. Velpeau tried the method twice; transferring the vein from before backward, and then bringing out the suture again from behind, as Dr. Fricke recommends; but, as a good deal of phlegmoseous inflammation followed, M. Velpeau thinks that if this plan be selected, the needle should be passed only one direction in making the suture, as in Dr. Fricke's operation for the cure of varicocoele. (*See Malgaigne, Op. cit.*, p. 163.)

The application of tincture of iodine to the skin covering varicose veins has been suggested. I have seen it tried in University College Hospital, but without any benefit, except when might be ascribed to quiescence in the recumbent position, adopted in conjunction with it.

In surgical operations, when large veins are divided, or may ever flow; and, if in considerable quantity, the patient is seriously destroyed. I believe that the first instance in which such a catastrophe was partially averted, and accounted for, took place in the practice of Dupuytren. The experiments made by M. Ponselle led him to infer, that arteries only insinuate themselves into such veins as are provided with valves. (*Journ. Répt. de Méd. et de Chir.*, 1851.) but wounds of veins, in all many different situations, have sometimes been followed by this occurrence, that the foregoing inference is

not admissible; too, as the air takes the course of the blood, it is likely that the presence of valves would make such a difference. Thus, patients are stated to have been suddenly destroyed, or brought into most imminent danger, from the rush of air into veins, in operations performed by Dupuytren and Beauchamp, about the neck and shoulder. (*Piedagot, Thèse, Paris*, 1827; and *Archiv. Gén. de Méd.*, t. v, p. 424.) on the thyroid gland, by Gosselin, (*Journ. de Physiol. Exp. et Médicale*, 1829,) on the shoulder, by Costara, (*H. Semestre, Thèse, Strasbourg*, 1829;) and Delpsch, (*Ann. de l'Hôpital de St. Louis, 2de Année*, p. 64.) on the breast and axilla, by Dr. Warren, (*Gaz. Méd. de Paris*, Mars, 1833;) Sir Ashley Cooper and M. Guérin, (*Thèse, Paris*, 1834;) above the clavicle, by M. Roux, (*Journ. Médical*, t. 32, p. 165.) at the armpit and on the chest, by M. Clémont, (*Lancette Franç.*, 1831;) and on the face, by Dr. Mott, (*Amer. Jour. of the Med. Sciences*, Nov. 1828.) (*See Alf. Velpeau, Anat. Chir.*, t. i, p. 156, 2vo, Paris, 1828.)

Some of the cases here referred to, however, I think, will not be generally acknowledged as clear and unambiguous examples of death or urgent peril from the entrance of air into the veins, though others seem to admit of no question. These seem to me to leave no doubt of this being the occasional cause of death; but did any ambiguity exist upon the subject, it would be dispelled by the experiments instituted on animals in relation to this point, by M. Magrader and Piedagot.

The greater number of examples of death or imminent peril from the admission of air into the veins, have certainly occurred in operations about the neck. Hence, even in opening the external jugular vein, Baron Larrey's advice, not to discontinue the pressure on that vessel before the opening, until a compress has been applied, is well deserving of being attended to; for otherwise a slight operation might be converted into a suddenly fatal wound. (*See Alf. Velpeau, Anat. Chir.*, t. i, p. 491.)

The particulars of a similar disastrous accident, which happened in the practice of M. Roux, may be read in a modern work. (*See Light Jour. of Med. Science*, vol. iv, p. 474.) The patient in this case revived, however, and lived seven days afterwards. (See other cases detailed by Dr. Warren, in *Amer. Cyclop. of Pract. Med. and Surgery*, ed. by Dr. Hays.) In one of these, the temporal artery was opened, and the patient, after being insensible for two hours, recovered. In another, where the air had entered a vein divided in the scalp, the patient, a woman, aged 33, was lost, notwithstanding the use of external and internal stimulants, and even laryngotomy, as a last resource.—C.]

[Dr. J. C. Warren has operated upon thirty-nine cases of varicose aneurysm, and has variously employed the ligature, pin, and the division of the vein, adapting the method to the case. So far as I am from, he has had uniform and permanent success.]

Dr. Joseph Smith having witnessed several deaths at the Pennsylvania Hospital, from tying veins for the cure of varicose aneurysms, consulted with Sir Ashley Cooper, in representing this practice.

Dr. J. Watson, surgeon to the New York Hospital, applies a tourniquet to the limb, above the enlarged vessels, and then making an incision at several points, especially where the

veins anastomose, from the lower part of the thigh downwards, even as far as the foot, exposing the enlarged vein at the bottom of each incision, but without touching the vessel, until all the incisions have been made from above downwards. He then removes a small portion of each vein exposed, proceeding from below upwards, and applies pressure, so as to avoid hemorrhage. At each point he removes from half an inch to an inch of the enlarged vessel, thus completely interrupting the course of the blood. After thus excising the veins, the integuments are drawn together with adhesive straps, and a circular roller applied. The following day, if there be no contraindication, by great abundance in the limbs, the roller is passed over, and the limb dressed as with the starch bandage. The patient is kept in the horizontal posture for a fortnight, and the bandage remains undisturbed all this time. The limb being then exposed, the vessels are usually found to be completely united by adhesion, and the varicose vessels obliterated. In two cases, Dr. Watson has thus operated on both the external and internal saphenae at the same time, and no difficulty has attended the removal of the limb by the deep veins of the leg. The patients treated by this method, thus far, have had no return of the disease, and some

of them have been cured nearly a year. In many cases of varicose veins, Dr. Watson's plan will be found to possess great advantages over any other, and the operation is certainly creditable to his skill and science. It is certainly less dangerous, less tedious, and if successful in effecting a radical cure, of which his experience thus far is in evidence, it must soon supersede the ligature, the pila, the seton, or the caustic.

Dr. Mutter has frequently performed Ricord's operation for varicose veins, by substantial ligature, and with gratifying results. He expresses himself greatly pleased with this method.

Dr. Parker, of New York, was the first surgeon in America who practiced the substantial ligation of varicose veins, which he did successfully in 1831. He has also treated chancre in the same way, and with the like success.

Dr. Arnshy, of Albany, has adopted a modification of Sir B. Brodie's operation, by the substantial division of varicose veins, and with entire success. He applies a fine bandage to the limb, over its whole length, and continues it for weeks afterwards, with a graduated compression over the wound.—*Review.*]

W.

[WRY-NECK. As early as the year 1759, a case of wry-neck and distortion of the jaw, caused by contraction of the platysma myoides, was cited by division of that muscle. (See Bienenbach, in *Lancet*, for Sept., 1835.)

M. Guérin, of Paris, has devoted great attention to this interesting subject, and Dr. John Mason Warren, of Boston, has published a paper on the subject, in the *Boston Med. and Surg. Journ.*, for Sept. 25, 1841, abounding with valuable matter, both of a critical and practical character. He avails himself of the exposition published by M. Guérin, on the pathology, physiology, and surgical treatment of wry-neck. Dr. Warren has operated twice with the most gratifying success, and upon formidable cases, requiring the division both of the sternal and clavicular portions of the sterno-cleido-mastoid muscle, and in one, dividing the body of the muscle, just above its division, into its sternal and cleido-mastoid. In this case he was able to detach the muscle between the thumb and forefinger, and isolate it completely from the deep-seated parts; and he pursued the plan of Guérin, by cutting from within outward, on the subcutaneous method. In the other case, Dr. Warren employed a narrow, sharp-pointed bistoury, and cut from without inward, still, however, making but one incision, and dividing the sternal-mastoid, and then the cleido-mastoid, near their attachment, subcutaneously. His complete success is creditable to his science and skill.

In the reports of these cases, which are very carefully made, we find a confirmation of the anatomical changes and general deformities with which wry-neck is so frequently complicated, and all dependent upon the contraction of this muscle. The whole nervous system, as well as the soft parts, is found to be involved. There is an inclination of the cervical vertebrae

on the dorsal, of the dorsal on the lumbar, and of the lumbar on the sacral. The whole spinal column participating, there is an exarotation of the ribs on one side, and a protraction on the other. The face and head, especially on the side of the contracted muscle, are found to be atrophied, and an oblique position is communicated to the side of the face by the traction of the skin, resulting from the distortion. The eyeball also undergoes a rotation on its axis, so as to bring it into the horizontal direction, which occasions both a deformity and an obstruction to the vision for a time, after the restoration of the head to its normal position.

The morbid affections of the head and face are ascribed by M. Guérin to the distention which the great vessels of the neck undergo, before their entrance into the cranium. He also lays down the following propositions on the general subject:—

1st. The sterno-cleido-mastoid muscle constitutes, in fact, two distinct muscles—the sterno-mastoid and the cleido-mastoid.

2d. These two muscles are possessed of different functions, the sterno-mastoid being a flexor and rotator of the head, while the cleido-mastoid is essentially a muscle of respiration.

3d. In wry-neck the sternal muscle is principally affected.

4th. In the treatment of chronic wry-neck, owing to the shortening of the sterno-mastoid, the section of the sternal portion alone suffices to destroy the essential cause of the deformity.

M. Guérin regards acute cases as curable by the local application of antispasmodic and other medication, depending on it does simply on muscular contraction; but in chronic cases, he thinks a division of the muscle by reason of a fibrous degeneration, requires surgical interference. It is only in those latter that myotomy is necessary, and their long persistence

may render the division of both portions of the muscle necessary, as in the two cases reported by Dr. Warren, while in a majority of instances the sternid portion only will require to be divided, suitable mechanical means being subsequently employed, by bandaging and otherwise, such as will occur to any intelligent surgeon. Dr. Warren found in his cases, that to place the patient on an inclined plane for three or four hours daily, with the head secured by a bandage carried under the chin, and attached to the upper part of the board, was a valuable auxiliary. He recommends the narrow blunt-headed knife of Bozner as preferable for this operation.

The following cautions of Dr. Warren indicate the dangers of this operation, and will enable the surgeon to avoid them:—

In dividing the internal head of the muscle, we have occasionally lacerated the skin the anterior jugular vein as it passes across the neck, to enter the subclavian. This, however, is easily avoided by making the incision sufficiently near the clavicle. The external and internal jugular are protected by the sternohyoid and sternothyroid muscles, and could not be reached but by the point of the knife carefully introduced. In dividing the sterno-mastoid, the external jugular, which lies between the border of the muscle and the skin, may be wounded; this is avoided by raising the skin, and passing the knife with its cutting edge perpendicularly to the muscle, the vein being left between the back of the instrument and the skin. In dividing the body of the muscle, the external jugular is the principal vessel to be avoided, and with sufficient care may be easily left on the outside of the puncture necessary for introducing the knife employed in the operation.

The old operation for wry-neck, by making a transverse incision through the skin, exposing the fibres of the muscle, and then dissecting it layer by layer, ought never to be repeated, now that the comparative superiority of the subcutaneous incision has been so amply demonstrated. The inflammation and suppuration consequent upon the old method were severe and dangerous, sometimes fatal, from the pyæmic infiltration into the anterior mediastinum. So also the contraction of the cicatrix, after so severe a wound, often defeated the operation. Indeed, in many other operations, but especially in this, the principle of subcutaneous incision is to be regarded as one of the most important improvements of modern surgery. Its establishment is doubtless due to Stromeyer, who was led to its adoption in his earliest operations on club-foot,

by his anxiety to avoid the difficulties and dangers which Delpech had encountered in his unsuccessful case. This is the secret of Stromeyer's success, for in other respects he availed himself of Delpech's principles and practice as his guides.

Dr. Nathan R. Smith, of Baltimore, has operated successfully by myotomy for this disease several times since 1828, the date of his first case, and in his last two cases he has adopted the subcutaneous method, with manifest advantage over the former mode of operation.

Dr. Motl, of New York, has successfully divided the sterno-clavicular muscle five times for torticollis. He perfects the old method by cutting through the integuments, and dividing the muscle from without inwardly, with suitable caution, and then healing the wound by granulation, dressing it with lint. He saw M. Guérin repeatedly perform the subcutaneous section of this muscle in Paris, and witnessed its repetition again and again in the same patient, which was rendered necessary by the muscle reuniting when thus divided, a difficulty which is incidental to this plan, but against which this old method gives immunity. Besides, the subcutaneous section is necessarily hazardous, because of the proximity of the sheath containing the large vessels; and though M. Guérin cuts from without inward, and even from within outward, subcutaneously, and avoids the dangers alluded to, yet there are few beside himself who can do so with safety to the patient. The propriety of a subcutaneous incision, in immediate proximity to large vessels and nerves, when the eye of the surgeon cannot take cognizance of the wound inflicted by his knife, is very questionable. And moreover, the frequent failure to divide all the fibres of the muscle at a single operation, the difficulty of preventing them from uniting, and the necessity of repeating the hazards of the subcutaneous section again and again, are all valid objections against this method. Indeed, in myotomy, the same reasons for avoiding a wound of the integuments do not exist as in tenotomy.

Dr. Motl has lately treated a case of wry-neck dependent on paralysis of the sterno-mastoid on one side, so that by the action of the antagonist muscle the distortion was perpetuated, and had existed over a year, during which the lady had been treated unsuccessfully, both by local and general means. The paralyzed muscle was soft and perfectly inactive. The healthy muscle on the sound side being divided, the head was at once restored to its normal position, and the distortion has been permanently removed.—*RECAP.*]

* The editor ought to say, that several dissections, from eminent American surgeons, have been successfully obtained, as they failed to reach him in time.
